19.1 SUMMARY

Herbal dietary supplements have been used and studied over 5000 years ago by ancient civilizations such as the Chinese, Indian, Greek, Roman, and Egyptian, among others, for the prevention and treatment of various ailments. Today, the most popular traditional healing systems that utilize plant extracts are Chinese herbal medicine (zhōngyào and pinyin), Indian (ayurveda and siddha), traditional African medicine, Graeco-Arabic medicine (unani tibb), Native American medicine, classical Greek and Roman herbal medicine, Japanese (kampo), and so on. In spite of modern medical advances, herbal dietary supplements continue to be widely used for health maintenance, disease prevention, and even disease treatment. Sales of herbal dietary supplements in the United States have increased from ~\$4 billion in 1999 to ~\$5 billion in 2009.

New herbal products get to the market much faster than pharmaceuticals, as in the United States, these are considered “dietary supplements” and are subject to the regulation specified in the Dietary Supplement Health and Education (DSHE) Act of 1994, which provides a very different framework for the regulation of herbal products

when compared with pharmaceutical drugs in terms of establishing efficacy, safety, and postmarketing surveillance. Herbal products may contain a single herb or combinations of several different herbs and are defined as such by both FDA (United States Food and Drug Administration) and EMEA (European Medicines Agency) regulatory agencies. Herbal dietary supplement manufacturers, while responsible for ensuring the safety of the herbal product, are not required to submit evidence of safety or efficacy to the FDA before commercialization. In addition, these regulations do not require that manufacturers report adverse events to the FDA and nor is there a guideline on how safety should be established. Hence, there is no impetus for manufacturers of herbal products to characterize the ADME properties of an herbal formulation or assess the potential for herb–drug interactions.

Approximately 15 million adults in the United States use herbal dietary supplements for the treatment of health conditions or for health maintenance; however, only one third inform their physician of this use. One misconception among the general population is that these agents lack adverse effects since they are obtained from a natural source. As a result, these herbal dietary supplements are often coadministered with prescription drugs (e.g., anticancer, anticoagulants, cardiovascular, and antidepressants), which increases the potential of pharmacokinetic and/or pharmacodynamic herb–drug interactions that are not apparent until there is a clinical manifestation. St. John’s wort (SJW), a popular herb used in the treatment of depression, has been implicated in a number of clinically significant interactions with pharmaceuticals. Coadministration of SJW with cyclosporine, an immunosuppressant that has a narrow therapeutic index has been fatal; patients who had undergone heart and kidney transplants and stabilized with cyclosporine experienced organ rejection following administration of SJW.

Herb–drug interactions, like drug–drug interactions, can occur via a number of mechanisms. A classical approach to the study of herb–drug interactions involves the assessment of the effect of the herbal dietary supplement on the absorption, metabolism, distribution, and excretion (ADME) of the drug versus the effect of drug on the biodisposition of the herb. The ADME mechanisms for the known herb–drug interactions involve, in most cases, inhibition or induction of hepatic and intestinal drug-metabolizing enzymes of the cytochrome P450 (CYP) family and/or drug transporters such as P-glycoprotein (P-gp). With the increased use of herbal supplements, the incidences of herb–drug interactions are increasing due to several reasons. These include easy availability of the herbs with no requirements for a prescription, lack of awareness of safety issues combined with the general perception that the natural origin of these herbs makes them safe for use, and sometimes the limitations of modern medicine in improving the quality of life which drives the patient to self-medicate themselves with herbal dietary supplements. Therefore, assessment of the safety, efficacy, and potential for herb–drug interactions is warranted during the development of pharmaceuticals. However, unlike evaluation of drug–drug interactions, determining the potential for herb–drug interactions can be quite challenging for various reasons, which has been covered later in this chapter.

This chapter will provide a review of the potential for herb–drug interactions based on the literature reports for those herbs that are most popularly used in the United States. The herbs covered are aloe vera, American and Asian ginseng, bitter orange, black cohosh, cranberry, curcumin, danshen, dong quai, echinacea, evening primrose oil, garlic, ginger, ginkgo, green tea, kava, licorice, milk thistle, saw palmetto, Siberian ginseng, SJW, and valerian. Clinical studies and relevant human *in vitro* studies that

have evaluated metabolism- or absorption-based mechanisms to understand the interactions between these herbs and commonly used drugs are reviewed.

19.2 INTRODUCTION

The study and the use of herbal dietary supplements dates back over 5000 years. Herbal products have been used by ancient civilizations such as the Chinese, Indian, Greek, Roman, and Egyptian, among others, for the prevention and treatment of various ailments. At present, the most popular traditional healing systems that utilize plant extracts include traditional Chinese medicine (TCM), traditional Indian medicine (TIM) (consisting of ayurveda and siddha), traditional African medicine, Unnani Tibb, Native American medicine, and classical herbal medicine (Greek and Roman), and so on. Among the traditional healing systems, TCM and ayurveda herbs are being evaluated for efficacy and safety profiles with acceptable science-based approaches [1,2]. Recently, danshen dripping pill, a TCM, passed US FDA phase II clinical trials for a cardiovascular indication and is currently posed to undergo phase III clinical trials [3]. Benefits of curcumin, an ingredient of turmeric, an ayurvedic herb, and a common ingredient in Indian cuisine are being assessed systematically and data from a few phase I trials support the subsequent phase II trials for a few different indications such as Alzheimer's disease [4] and colorectal cancer [5]. The principles of TCM are based on the harmony of two opposite forces, namely Yin and Yang. When Yin and Yang are in disharmony, it results in disease. Harmony is maintained through acupuncture, massages (e.g., Shiatsu), diet, and herbal medicines [6]. Ayurveda recognizes the connection between the body, mind, and soul and believes that a balance of these three aspects is required for optimal health [1], which is achieved through diet, herbs, exercise (yogasana for the body and the mind), massage, and meditation.

In the United States, dietary supplements are defined by the 1994 Dietary Supplement Health and Education Act (DSHEA) [7,8], as products that are not used exclusively as food but are intended to be consumed in addition to an individual's diet. The law states that dietary supplements are taken by mouth and contain one or more dietary ingredients. Examples of dietary ingredients include vitamins, minerals, herbs, or other biological material, amino acids, and enzymes. Dietary supplements are required to be clearly labeled and may be sold in the form of tablets, capsules, powders, liquids, extracts, or teas. These products are often labeled as not having been approved by the FDA or that the product is not to be used to treat or diagnose a disease; yet, they are commonly used for a wide range of purposes including treatment of a disease state. Some of the common reasons for consumption of dietary supplements in the United States include supplementing a necessary substance not found in large enough quantities in the diet (e.g., vitamins), as a prophylactic for a disease or condition, for boosting the immune system, or as a tonic for improving general health (physical state such as stimulating weight loss etc., or mental state such as sharpening memory, etc.), and sometimes also for the treatment of a disease state. Herbs are defined as a part of the plant such as roots, stems, tree bark, leaves, flowers, fruits, or seeds or a product prepared from these plant parts. Herbal products may contain a single herb or a combination of multiple herbs.

The 20 top-selling herbal dietary supplements in the United States in 2009 include cranberry, soy, saw palmetto, garlic, echinacea, ginkgo, milk thistle, SJW, ginseng,

Figure 19.1 Herbal sales in United States from 1999 to 2009. *Source:* Adapted from *Herbal Gram*. 2010;86:62–65.

black cohosh, green tea, evening primrose, valerian, horny goat weed, bilberry, elderberry, grape seed, ginger, aloe vera, and horse chestnut [9]. Sales of herbal products has been on an upward trend from 2003 onward and increased from ~\$4.1 billion in 1999 to \$5.03 billion in 2009 as shown in Fig. 19.1.

Information presented in this chapter is limited to the commonly used herbal medicinal products that are commercially available in the United States. These will be referred to as *herbal dietary supplements* and do not include nutraceuticals such as vitamins and other dietary constituents. A list of the herbs covered herein for which absorption and/or metabolism-related interactions are reported with other commonly used drugs in humans, either *in vitro* or based on clinical data, are presented in Table 19.1.

19.3 REGULATORY PERSPECTIVES

Herbs are perceived as dietary supplements in the United States. A general outlook regarding herbs is that they are safe because they originate from a natural source. Hence, congressional action directed that herbs in the United States will be considered to be “dietary supplements” and will be regulated by the DSHEA of 1994, which was an amendment of the Federal Food, Drug, and Cosmetic (FDC) Act to establish standards with respect to dietary supplements and for other purposes [10]. Frankos *et al.* [11] have presented a concise review on FDA regulations pertaining to dietary supplements. It is interesting and important to understand the evolution of the federal regulations as it pertains to drugs, food, food additives, and dietary supplements and its role in ensuring public safety. Milestones in the history of the development of the current-day regulations are summarized below:

1. The history of the US federal regulation of foods and drugs began with the signing of the Pure Food and Drugs Act in 1906. This act sought to explicitly prohibit adulteration in foods, drinks, and drugs. In addition, this act provided regulations to ensure accurate labeling of products [12].
2. In 1938, “The Food, Drug, and Cosmetic Act” (FD&C Act) replaced the Pure Food and Drugs Act of 1906. The FD&C Act was the first law worldwide by

TABLE 19.1 List of Herbs with Absorption-Mediated or Metabolism-Mediated Effect of Herb on Commonly Used Drugs

Herb	Test System	Probe Drug	CYP/P-gp	Outcome	Mechanism	References
Asian ginseng (<i>Panax ginseng</i>)	<i>In vivo</i>	Debrisoquine	CYP2D6	Change in metabolite/parent ratio	Inhibition	Gurley <i>et al.</i> (2005) [67,79]

the FDA to require scientific safety testing before a drug could be approved for marketing and it placed the burden of proof on the manufacturer to do so [13]. This act was instituted in response to a 1937 tragedy when a Tennessee drug company marketed a new pediatric formulation of sulfanilamide in which diethylene glycol (DEG) was added as a solubilizer, which also served to make its taste appealing to the pediatric patients [14]. DEG had never been tested for safety before its use in this product and was responsible for over 100 deaths. In addition, the FD&C act established a category of foods for special dietary use and required that the labeling include information on the vitamin, mineral, or other dietary content.

3. Following the enactment of the FD&C Act of 1938, FDA attempted to regulate dietary supplements [15]. One approach undertaken was to classify these products as drugs based on health claims made on the label, while another was to publish regulations which required that the dietary supplement products be declared as drugs if containing potencies exceeding 150% of the US recommended daily allowance. This was followed by the vitamin and mineral legislation (the Rogers/Proxmire amendment) in 1976, prohibiting the FDA from limiting the potency or nutrient combination of vitamin and mineral supplements and from classifying them as drugs based solely on their potency or combination.
4. Another landmark in the legislative history of dietary supplements is the 1990 "Nutrition Labeling and Education Act" (NLEA) [16]. It required that the labels of all packaged foods contain nutrient information and allowed the FDA to establish the appropriate scientific evaluation and approval standards needed. The FDA chose to ensure that standards set for dietary supplements would be similar to that needed for drug approvals (Dietary Supplement Act of 1992). As required by this act, the FDA put forth "A Notice of Proposed Rule" (ANPR) in 1993. The guidelines within this act regulated certain dietary supplements as drugs. The ANPR elicited considerable protest from the public and the dietary supplement industry because FDA appeared to be reproposing regulatory provisions withdrawn or struck down by court actions in previous years. The ANPR was a significant motivating factor in industry and congressional effort to develop and pass the DSHEA of 1994.
5. The purpose of DSHEA was to allow the public increased access to these products that would otherwise have been curtailed if they had been subject to the same regulations as the pharmaceuticals, while still allowing the FDA to intervene if there are safety issues, false claims, or adulteration. These regulations provide a very different platform compared to the pharmaceuticals for establishing efficacy and safety and for conducting postmarketing surveillance. Under this Act, manufacturers of herbal products are responsible for ensuring the safety of the herbal product; however, they are not required to provide proof of safety and efficacy to make certain limited claims regarding the use of the herb. Also, these regulations do not require that manufacturers report adverse events to the FDA, and they do not specify how safety should be established. Hence, there is no impetus for manufacturers of herbal products to characterize the potential for herb-drug interactions.

Key features of this act include the specific categorization of dietary supplements as food; clarification that dietary supplements are not food additives and

hence not subject to premarket safety testing and FDA approval, ensures the current good manufacturing practice (cGMP) regulations for dietary supplements and allows certain statements of well-being claims without obtaining premarket authorization from the FDA. The dietary supplement and nonprescription drug consumer protection act of 2006 required dietary supplement companies to report adverse events to the FDA and since 2008 to list an address or phone number on dietary supplement product labels that customers can use to report serious adverse events and report to the FDA.

The DSHEA defines a dietary supplement as “a product (other than tobacco) intended to supplement the diet that bears or contains one or more of the following dietary ingredients: (A) a vitamin; (B) a mineral; (C) an herb or other botanical; (D) an amino acid; (E) a dietary substance for use by man to supplement the diet by increasing the total dietary intake; or (F) a concentrate, metabolite, constituent, extract, or combination of any ingredient described in clause (A), (B), (C), (D), or (E).” A dietary supplement is further defined as “a product that is intended for ingestion in the form of capsule, powder, soft gel, gel cap or other form, if not represented for use as a conventional food item or as a sole item of a meal or a diet, and contains one or more dietary ingredients and is labeled as a “dietary supplement”.”

6. To address the deficiencies within the DSHEA, Gershwin *et al.* [14] have put forth a proposal to have dietary supplement manufacturers submit human safety data for premarket approval by the FDA. Their proposal has a number of benefits which include allowing the FDA to fulfill its mission of consumer protection for dietary supplements, to address concerns of the mainstream medical community, to minimize toxicities, to resolve consumer confusion, and to restore consumer confidence. In addition, Collins *et al.* [17] reported differences between dietary supplement containing ω -3 fatty acid and those ω -3-fatty acid formulations that are available by prescription, thereby further emphasizing the need for dietary supplements to be regulated in a manner similar to pharmaceutical drugs.

19.4 GENERAL ISSUES WITH ASSESSMENT OF HERB-DRUG INTERACTIONS

It has been a regulatory requirement to conduct different *in vitro* and, if necessary, clinical studies to assess a drug's potential for causing interactions with other drugs that are typically coadministered. This information is presented in the label of the drug product. However, a quick review of the drug product labels for products entering market in the past five years demonstrates that information regarding the potential for adverse effects or lack of efficacy due to interaction of the drug with an herbal dietary supplement arising from their concomitant use is lacking. Bent and Ko [18] have reviewed the contributing factors for the challenges associated with obtaining improved confidence with herbal products.

When approaching the study of herb-drug interaction, there are two main questions. The first is what does the drug do to the biological fate of the herb? Given the extent of information currently available, this question is rather difficult to answer, as the biodisposition of the herb including the pharmacokinetic (PK) characteristics is often not very well characterized. The second question is what does the herb do to the

biodisposition of the drug? Theoretically, this question can be addressed, albeit not without significant challenges (presented below) to interpreting the data in a clinically relevant manner and these are listed below.

Most herbal dietary supplements are isolated from a natural source such as roots, tree bark, stem, leaves, flowers, fruits, or seeds by one or more processes of extraction. As a result, they contain multiple chemical constituents that may include alkaloids, glycosides, flavonoids, sterols, saponins, tannins, and terpenes [19]. In most cases, more than one compound contributes to the therapeutic activity. Some herbal products also contain multiple herbs as it is believed that they exert complementary effects. In most cases, the active ingredient(s) is not known. Hence, assessment of herb–drug interaction is not quite relevant to the clinical scenario if performed with just a single compound that is known to be the lead compound for eliciting pharmacological effect. Therefore, a mixture of all the chemical constituents that is present in the final herbal dietary supplement needs to be utilized in the assessment of interaction potential to be representative of the clinical scenario. However, it is not an easy task to maintain consistency with respect to the type of chemical constituents and their concentrations between batches.

1. *Interbatch Consistency for Potency:* Several environmental factors, such as the location of the plant, altitude, the quality of the soil, variation in temperature, extent of rainfall, shade, dew, humidity, frost, as well as chemical treatment (fertilizers, pesticides, antimicrobials, etc.) can influence the chemical composition that is found in the plant extract. Hence, it is very common to have batch-to-batch variation with respect to both the types of compounds present in the extract as well as their concentrations. For example, analysis of 25 ginseng products that were commercially available demonstrated a 15- to 200-fold variation in the concentration of the two ingredients that are believed to be active [20]. Some manufacturers utilize the process of standardization, whereby several batches of the herb containing differing amounts of the active ingredient are combined in an effort to obtain the desired concentration of the active ingredient in the product. While such an approach provides for minimal interbatch variation in the dose of the active ingredient, the rest of the presumed nonactive components remain highly variable and the risk for alteration in the biodisposition and safety of the coadministered drug still exists, if the rest of the compounds in the herbal product contribute to an herb–drug interaction.
2. *Contaminants:* Contamination and adulteration of herbal products have been reported to be an issue after chemical analysis of some TCMs and ayurvedic herbal products [21–26]. In particular, these preparations were found to contain lead, mercury, and arsenic at levels that would result in serious health problems if taken at recommended doses. The contamination of herbals with pesticides, bacteria, molds, fungi, and mycotoxins can also result in health issues [27]. These contaminants present the potential for alteration of the true potential of the herbal product to interact with the drug-metabolizing enzyme being assessed and should be considered in the interpretation of data.
3. Most clinical trials that have been conducted with herbal products offer limited utility due to small sample size, less rigorous study design, and most importantly use of products where the composition is not very well defined [28].

4. The percentage of patients who self-medicate with herbal products and volunteer the information to physicians is alarmingly low presumably due to the perception that they are taking something perceived to be “safe” [29,30]. Hence, it is very likely that a clinically reported adverse event that may have been caused due to alteration of the drug PK by the herb would not be investigated as an herb–drug interaction due to lack of accurate patient history.
5. The regulatory status that herbs are assigned in the United States, that is, as dietary supplements, does not require manufacturers of herbal products to evaluate the potential for herb–drug interactions.
6. Assessing the PK of herbal drugs is fairly complex due to multiple bioactive compounds in the product as well as due to the dose of a single compound being in the lower milligram range due to which the plasma concentrations are often very low (picogram to nanogram per liter). Hence, the bioanalytical methods need to be very sensitive to assess the PK of the major constituents of the herb.

These facts make evaluation of herb–drug interaction relatively challenging when compared to the typical assessment of drug–drug interaction(s) during the development process of a pharmaceutical drug product.

19.5 UNDERLYING MECHANISMS FOR HERB–DRUG INTERACTIONS

For most herb–drug interactions, the potential for such an interaction is not known until it manifests clinically in the form of adverse effects or lack of pharmacology of either the drug or the herb. Theoretically, both PK and pharmacodynamic (PD) mechanisms may be implicated; however, this chapter focuses on the PK-based mechanisms only. Alteration in the PK of the drug due to interaction with the herb can occur at the level of ADME. This chapter focuses on the herb–drug interactions that arise out of interaction of the herb with a transporter for which the drug is also a substrate or those which are metabolism mediated. The PK profile of many drugs is known to be altered by coadministration of herbal products which is mediated by the herb by either altering the absorption of the drug or by inhibiting or inducing the drug-metabolizing enzymes, most commonly the CYP enzyme(s), which contribute to the metabolism of the drug. Butterweck and Derendorf [31] have presented a review article on this subject.

19.5.1 Absorption-Based: Herb–Drug Interactions due to Association with Transporters

Clinically reported interactions of herbal dietary supplements with concomitant administration with drugs have been reported for several drugs. Examples include cyclosporine, tacrolimus, imatinib, irinotecan, digoxine, fexofenadine, simvastatin, saquinavir, and indinavir, which are known to be substrates for P-gp, also known as *multidrug resistance protein* (MDR1) or ABCB1, a well-researched drug transporter protein [32] that is described in the chapter titled *ABC Drug Transporters and their Impact on Drug Disposition/Drug Sensitivity and Resistance*. P-gp mediates the ATP-dependent efflux of drugs from cells, is expressed in a number of tissues, and is responsible for the transport of an extremely large number of substrates [33]. P-gp presents a high transport capacity and broad substrate specificity: a number of

clinically relevant drugs with structurally different features and belonging to different classes (examples include digoxin, loperamide, berberine, irinotecan, doxorubicin, vinblastine, paclitaxel, and fexofenadine) can be effluxed by P-gp [34]. Substrates of P-gp are generally hydrophobic molecules either cationic or neutral [33–35].

Some P-gp drug substrates are able to inhibit P-gp-mediated transport of other substrates leading to potential drug–drug interactions [35–38]. A number of herbal supplements used by cancer patients in combination with cancer drugs have been reported to modulate P-gp expression and/or activity [39]. Piperine from black pepper and silymarin from milk thistle were reported to inhibit P-gp activity *in vitro* [39]. Curcumin from turmeric and several catechins from green tea were shown to reduce P-gp expression and activity *in vitro* [40]. Using the *in vitro* caco-2 cell model, Hou *et al.* reported that 30 μ M concentration of curcumin increased the accumulation of rhodamine 123 (a P-gp substrate) by approximately twofold in the receiver cell similar to verapamil, a known P-gp inhibitor [41]. In this study, curcumin inhibited P-gp expression and rhodamine efflux by about 30% and the authors proposed that curcumin inhibits the AP-1 (activator protein-1) transcriptional factor and NF- κ B (nuclear factor- κ B), which regulates MDR1 expression. Terhaag and colleagues conducted a clinical study with a randomized, open-labeled design using 12 healthy volunteers and a wash out period of one week between the administration of a single oral dose of 50 mg talinolol and the concomitant administration of curcumin (300 mg/day for six days) and a single oral dose of 50 mg on day 7 [42]. The effect of curcumin administration on talinolol PK was a 53% increase in oral clearance and decreases in both area under the concentration curve (AUC) and $C_{\max}$ (by 33 and 28%) compared to administration of talinolol alone. The authors attributed the observed decrease in talinolol AUC and $C_{\max}$ to low intraluminal concentration of curcumin or to upregulation of ATP-binding cassette transporters such as MRP2. One of the challenges with predicting absorption-related interactions is sometimes the lack of *in vitro* to *in vivo* correlation as demonstrated by the talinolol—curcumin example. Han and colleagues [43] conducted a clinical study to investigate the effect of concomitantly administered silymarin on the PK of talinolol in healthy Chinese volunteers and its association with a *MDR1* C3435T genetic polymorphism. Eighteen healthy adult men (six *MDR1* 3435CC homozygotes, six *MDR1* 3435CT heterozygotes, and six *MDR1* 3435TT homozygotes) were recruited in a two-phase, randomized, single-blind, crossover design. The PK of talinolol was measured after coadministration of placebo or 140-mg silymarin capsules three times daily for 14 days. The peak plasma concentration ($C_{\max}$) of talinolol was significantly higher after silymarin administration as compared with placebo ($p = 0.007$). The area under the plasma concentration-time curve of talinolol from 0 to 36 h (AUC_{0-36h}) and when extrapolated to infinity ($AUC_{0-\infty}$) was increased by $36.2 \pm 33.2\%$ and $36.5 \pm 37.9\%$, respectively, by silymarin coadministration. The oral clearance (CL/F) of talinolol was decreased by $23.1 \pm 16.6\%$ ($p < 0.001$) during the silymarin-treated phase. No change in the time to peak concentration ($t_{\max}$) and the blood elimination half-life ($t_{1/2}$) of talinolol was observed between the placebo and silymarin-treated phases.

Studies indicate that P-gp expression, similar to CYP3A, is inducible. CYP enzymes and P-gp are regulated via the pregnane X-receptor (PXR), which controls the transcription of their genes (P-gp encoded by *MDR1*). Herbal dietary supplements can modify the first-pass effect for drugs through changes in the PXR activity or by direct competitive or allosteric interference at the active substrate-binding regions of CYP enzymes and transport proteins [44].

SJW induces the activity of intestinal CYP3A4 and P-gp via the common regulator PXR [45]. In addition, some SJW constituents inhibit CYP isoenzymes (1A2, 2C9, 2C19, 2D6, and 3A4) [46]. Therefore, an initial inhibition of human CYP3A4 by SJW leads at first to an increased bioavailability of CYP3A4/P-gp substrates, such as digoxin or fexofenadine [47,48], but is then followed by a decrease in bioavailability due to enzyme induction. Hyperforin has been identified as the constituent in SJW responsible for PXR-mediated stimulation of CYP and P-gp. Guggul (*Commiphora mukul*), a resin, from the mukul tree is approved as a cholesterol-lowering drug in India and is known to induce the expression CYP3A4 and P-gp to a similar extent to SJW [49].

Cell lines such as caco-2 that express P-gp and inside-out membrane vesicles prepared from these cell lines can be used to determine whether a drug is a P-gp substrate or inhibitor. Mice deficient in Mdr1a or Mdr1a/b are also used for assessing the role of P-gp *in vivo*. Knockout mice may be used as a reference for complete inhibition of P-gp [50]. The clinical significance of a P-gp inhibitor can be investigated in humans by assessing P-gp-mediated clearance or exposure using digoxin as a model probe substrate [51].

Mardin–Darby canine kidney (MDCK) cell lines stably expressing organic anion transporters (OATs) such as OAT1, OAT3, and OAT4 have been used to assess *in vitro* the potential for renal transport of anionic drugs [52]. Mouse knockout models (OATP1b) for *in vivo* experiments have also been developed and reflect more closely activity associated with OATP1B1 and OATP1B3, respectively [53]. Aristolochic acids present in some TCM preparations have been shown to inhibit human OAT1, OAT3, and OAT4 [54].

In vitro cell-based and *in vivo* mouse-based knockout mice are used to assess substrates and inhibitors of the breast cancer resistance protein (BCRP) transporter [53]. Tamaki *et al.* [55] evaluated the inhibitory effects of nine herbal extracts on BCRP-mediated transport using *in vitro* membrane vesicles isolated from mammalian cells expressing wild-type BCRP (SB-BCRP-M-VT) and methotrexate as a BCRP-specific probe substrate. Extracts of soybean, black cohosh, rutin, and passion flower almost completely inhibited BCRP-mediated transport of methotrexate at 100 μ M and chlorella, milk thistle, and Siberian ginseng inhibited BCRP-mediated transport of methotrexate by 22, 45, and 36%, respectively [55].

19.5.2 Metabolism-Based: Herb–Drug Interactions due to CYP Inhibition

There have been several clinical reports of herb–drug interactions arising due to inhibition of one or more of the CYPs commonly responsible for drug metabolism. Typically, an increase in side effect(s) will be expected if an herb has the potential to inhibit metabolism of a drug, thereby decreasing metabolic clearance of the drug and increasing plasma drug concentration. The commonly used *in vitro* and *in vivo* methods of assessing the potential for drug–drug interaction [56] can also be employed to evaluate the potential for herb–drug interaction with the exception of *in silico* methods. Since the utility of *in silico* methods to predict the binding properties of ligands to mammalian CYPs lies in having knowledge of the chemical structure of the bioactive molecule (drug/herb), the identity of the pharmacologically active molecule in the herb needs to be known. Since most herbs contain multiple bioactive compounds,

application of *in silico* methods and data interpretation to predict clinical herb–drug potential is not as straightforward.

19.5.3 Metabolism-Based: Herb–Drug Interactions due to CYP Induction

If an herb causes induction of a CYP that is responsible for the metabolism of the drug, it will result in increased metabolic clearance of the drug. Typically, this results in reduced pharmacological effect or lack of therapeutic effect of the drug, since, with a few exceptions, most metabolites are usually less pharmacologically active than the parent drug. Although the commonly employed experimental methods can be used to assess herb–drug interactions, the limitations posed due to the inherent nature of the herbal products applies here as well, as discussed above in Section 19.3. Examples of drug interactions that occur due to induction of CYP enzymes after administration of herbal products, such as SJW, are reported on the FDA website. The warning reported on the FDA web site for SJW is “This herb is considered an inducer of liver enzymes, which means it can reduce the concentration of medications in the blood. SJW can reduce the blood level of medications such as Lanoxin, the cholesterol-lowering drugs Mevacor and Altocor (lovastatin), and the erectile dysfunction drug Viagra (sildenafil)” [57].

19.6 COMMONLY USED HERBS IN THE UNITED STATES OF AMERICA

The 20 top-selling dietary supplements in the United States according to information resources incorporated in 2009 include cranberry, soy, saw palmetto, garlic, Echinacea, ginkgo, milk thistle, SJW, ginseng, black cohosh, green tea, evening primrose, valerian, horny goat weed, bilberry, elderberry, grape seed, ginger, aloe vera, and horse chestnut [9]. The market information firm SPINS of Schaumburg, Illinois, has a slightly different list of top 20 selling dietary supplements for 2009 and include aloe vera, flaxseed, wheatgrass, acai, turmeric, milk thistle, stevia, elderberry, saw palmetto, Echinacea, garlic, Echinacea with goldenseal combination, oregano oil, valerian, ginkgo, chlorophyll/chlorella, black cohosh, cranberry, evening primrose, and green tea [9]. In this chapter, we have covered a number of the top 20 selling herbal dietary supplements from both sources and in addition covered popular traditional Chinese herbals, dan-shen and dong quai. A more recent comprehensive review of clinical evidence for drug–herb interactions has been presented in a review article by Kennedy and Seely [58], while Izzo and Ernst [59] have reviewed preclinical data to determine the potential for herb–drug interaction in addition to the clinical data. Relevant herb–drug interactions reported in the literature in humans, *in vitro* and clinically, are summarized in Table 19.1.

19.6.1 Aloe (*Aloe vera*, Family Asphodelaceae)

The succulent leaf of *Aloe vera* contains clear gel which has skin healing and soothing properties in addition to moisturizing when used topically for minor cuts and burns including sunburns [60,61]. *A. vera* juice or capsules are also being used orally in the treatment of diabetes, asthma, epilepsy, and osteoarthritis because of its anti-inflammatory effect [62,63]. This herb is very widely used orally as an adjunct treatment

of diabetes II; there are no published clinical reports of ADME-based interactions with other drugs.

19.6.2 American and Asian Ginseng (*Ginseng* sp., Family Araliaceae)

The root of ginseng is believed to have a number of different therapeutic uses and is most often used in dried form, either whole or sliced. Ginseng leaf is sometimes used, also in the dried form. The Asian ginseng (*Panax ginseng*) and the American ginseng (*Panax quinquefolius*) are taken orally and used as nourishing stimulants (such as in energy drinks), anti-inflammatory, for prevention of cancer, and in the treatment of erectile dysfunction in men due to their vasodilating effect [64]. The active ingredients are ginsenosides.

In vitro assessment of some of the active ingredients of ginseng in cDNA-expressed CYP system showed that ginsenoside Rd caused weak inhibitory activity against CYP3A4 (with IC₅₀ values of 58 and 74 μ M for two different substrates) and CYP2D6 (IC₅₀ of 76 μ M) and even weaker inhibition of CYP2C19 and CYP2C9 activities with IC₅₀ values over 100 μ M, while ginsenoside Rc increased the activity of CYP3A4 (~1.5-fold) and CYP2C9 (~1.7-fold), although assay artifact was not completely ruled out [65]. Clinical studies have shown that ginseng does not have the potential to cause CYP- or P-gp-based drug interactions [66–71] except for some slight changes observed in metabolite-to-parent ratio when using debrisoquine as a CYP2D6 probe after pretreatment with *P. ginseng* in a study reported by Gurley *et al.* [67]. It has been reported clinically that concomitant use of *P. ginseng* and phenelzine resulted in mania for which the mechanistic basis is not known, however, thought to be pharmacological [72,73]. A few clinical cases have been reported of ginseng affecting platelet aggregation when coadministered with warfarin, which are considered to have a pharmacological basis [74].

19.6.3 Bitter Orange (*Citrus aurantium*, Family Rutaceae)

Bitter orange is included in several herbal weight loss products and is believed to possess antioxidant properties, although a literature review reported by Bent *et al.* [75] determined that the weight loss produced by treatment with bitter orange was not statistically significant. The effect of bitter orange on the CYP isozymes was evaluated by Gurley *et al.* [76] after daily dosing for 28 days, and it was observed that there was no change in the CYP activity.

19.6.4 Black Cohosh (*Actaea racemosa*, Family Ranunculaceae)

The dried roots of Black cohosh (formerly known as *Cimicifuga racemosa*) contain glycosides, isoferulic acids with anti-inflammatory effects, and phytoestrogens, among several other active substances [77]. Hence, it is often used as an antirheumatic and antispasmodic as well as to treat dysmenorrhea and to ease menopausal symptoms [78].

At a dose of 2180 mg/day taken for 28 days, which is significantly higher than the recommended daily dose of 40–200 mg, a clinical study reported by Gurley *et al.* [79] using CYP-selective probe substrates for CYP1A2, CYP2D6, CYP2E1, and CYP3A4 showed that there was no effect of black cohosh on CYP1A2, CYP2E1, and CYP3A4. However, a weak inhibition of CYP2D6 was clinically observed based on altered PK of

debrisoquin as the probe substrate in the same study. A later study, also conducted by Gurley *et al.* [80], using the same probe, showed that black cohosh after a daily dose of 80 mg for 14 days did not inhibit CYP2D6. Another clinical study, also reported by Gurley *et al.* [81], confirmed the absence of any CYP3A4-mediated interaction based on midazolam PK, although the dose of black cohosh was relatively lower (80 mg/day for 14 days). Clinical evaluation of digoxin PK after 40 mg/day dose for 14 days with black cohosh showed no potential for black cohosh to elicit drug interaction due to P-gp inhibition [82].

19.6.5 Cranberry (*Vaccinium macrocarpon*, Family Ericaceae)

The ripe fruits of Cranberry are known for anticoagulant, anti-inflammatory, and antimicrobial properties including antiparasitic activity. It is often used as a prophylaxis and/or treatment of urinary tract infections [83].

Six clinical studies have been reported for herb–drug interactions with cranberry administered either in the form of juice (5 of 6 studies) or in the form of a capsule (one of six studies) containing concentrated extract of cranberry. Cranberry juice did not alter the PK of flurbiprofen [84], cyclosporine [85], midazolam [86], tizanidine [86], and warfarin [86–88]. However, the area under the international normalized ratio (INR)–time curve (AUC_{INR}) for warfarin was slightly increased (30% increase) when capsules of concentrated cranberry extract (daily dose of 3 g for 14 days) were used as reported by Abdul *et al.* [89]. In this study, there was no impact on baseline INR, warfarin PK, or platelet aggregation suggesting that cranberry pretreatment did not have a significant effect on the clotting of blood.

19.6.6 Curcumin (*Curcuma longa*, Family Zingiberaceae)

Curcumin, a hydrophobic polyphenolic compound belonging to the curcuminoid class [90], is one of the principal active ingredients of turmeric which is a commonly used spice in Indian cuisine as well as a coloring pigment. Turmeric is obtained from the dried rhizomes of *Curcuma longa* and has been used for its medicinal properties in ayurvedic medicine for centuries. More recently, systematic study of the pharmacology of curcumin has gained interest due to evidence that it has anti-inflammatory, antioxidant, antiviral, antifungal, and anticancer properties [91,92]. Curcumin has potential against various malignant diseases such as diabetes mellitus, arthritis, and Alzheimer's and has been described as the "ideal spice for life" by Aggarwal *et al.* [93]. Baum *et al.* [94] showed that oral doses of up to 4 g/day for six months were found to be safe. Cheng *et al.* [4] demonstrated that curcumin is not toxic to humans up to 8000 mg/day when taken by mouth for three months. This study as well as another clinical study conducted by Sharma *et al.* [5] provided preliminary evidence that curcumin has the potential to serve as a chemopreventive agent for cancer.

Appiah-Opong *et al.* [95] studied the interactions of curcumin, a mixture of its decomposition products, and four of its individually identified decomposition products (vanillin, vanillic acid, ferulic aldehyde, and ferulic acid) on five major human drug-metabolizing CYPs using human recombinant CYPs *in vitro*. It was observed that curcumin strongly inhibited CYP2C9 (IC_{50} 4.3 μM) and showed moderate inhibition of CYP3A4 and CYP2B6 with IC_{50} values of 16.3 and 24.5 μM , respectively. Curcumin was observed to be a noncompetitive inhibitor of CYP2C9 (K_i 11.5 $\pm$ 0.8 μM),

whereas inhibition of CYP3A4 (K_i $7.4 \pm 3.5 \mu\text{M}$) and CYP2B6 (K_i $33.2 \pm 14.0 \mu\text{M}$) was of a competitive type. In a separate study reported by Volak *et al.* [96], curcumin as well as curcuminoid extract and curcuminoid mixture were evaluated *in vitro* for its potential effects on drug-metabolizing enzymes *in vitro*. In their study, they determined that curcumin was a potent inhibitor of sulfotransferase (SULT) > CYP2C19 > CYP2B6 > UDP-glucuronosyltransferase (UGT) > CYP2C9 > CYP3A with IC_{50} values ranging from 0.99 ± 0.04 to $25.3 \pm 1.3 \mu\text{M}$. SULT inhibition study with curcumin was conducted in LS 180 cells, CYP studies in human liver microsomes and UGT separately in both LS 180 cells and human liver microsomes. The inhibition of CYP3A activity by curcuminoid extract was determined to be competitive inhibition (K_i of $11.0 \pm 1.3 \mu\text{M}$) which was consistent with the results reported by Appiah-Opong *et al.* [95], whereas mixed competitive–noncompetitive inhibition was attributed to the inhibition of CYP2C9 and CYP2C19 activities with corresponding K_i values of 10.6 ± 1.1 and $7.8 \pm 0.9 \mu\text{M}$, respectively.

Chen *et al.* [97] conducted a clinical study in healthy male volunteers by administering 1 gm of curcumin orally (once daily) for 14 consecutive days and on the 15th day coadministering with 100-mg caffeine. Curcumin was shown to inhibit CYP1A2 activity by 28.6% as measured by decreased formation of caffeine metabolite, 1,7-dimethylxanthine. An increase (48.9%) in CYP2A6 activity was also observed in this study. Additional clinical studies are needed to fully validate curcumin's ability to interact with pharmaceutical medications by inhibition of CYP1A2 and other drug-metabolizing enzymes.

19.6.7 Danshen (*Salvia miltiorrhiza*, Family Lamiaceae)

Danshen is the dried root or rhizome of *Salvia miltiorrhiza*. It is primarily used for the treatment of cardiovascular diseases, including angina pectoris, stroke, and myocardial infarction [98]. The major active components of danshen are tanshinones.

Tanshinones are substrates for P-gp and are potent competitive inhibitors of CYP1A2 with K_i of less than $1 \mu\text{M}$ [39]. Izzat *et al.* [99] reported that patients on chronic warfarin therapy with coadministration of danshen had enhanced anticoagulation and bleeding. Additional clinical studies are needed to demonstrate that inhibition of warfarin metabolism (i.e., through inhibition of CYP2C9) may result in the enhanced anticoagulation observed in combination therapy with danshen. Qui *et al.* [100] reported that danshen induces CYP3A4 in healthy volunteers. Midazolam oral clearance in this study increased by 35% and C_{max} and AUC decreased by 31 and 27%, respectively.

19.6.8 Dong Quai (*Radix angelica sinensis*, Family Apiaceae)

Dong quai, a root preparation, is used to treat menstrual cramps, regulate menstrual periods, and lessen menopausal symptoms. Dong quai is thought to promote natural progesterone synthesis, a hormone that declines during menopause. It has also been reported to have medicinal use in certain cardiovascular conditions. The root of this herb is used to treat fatigue, anemia, and high blood pressure [6].

Sevior *et al.* [101] reported that dong quai inhibited CYP2B6 and CYP2C19 *in vitro* in human liver microsomes with IC_{50} values ranging between 3 and $5 \mu\text{M}$. Clinical herb–drug interaction studies involving dong quai and substrates of CYP2C19 and CYP2B6 need to be conducted to determine if the interactions are clinically relevant.

In a clinical study conducted by Page and Lawrence [102], coadministration of dong quai and warfarin increased the anticoagulant effect of warfarin resulting in higher INR ratios. It has been hypothesized that this effect is PD rather than PK. Additional studies are needed to understand the risks associated with coadministration of dong quai and other blood thinning agents.

19.6.9 Echinacea (*Echinacea* sp., Family Asteraceae)

Roots and sometimes other plant parts from multiple species of the *Echinacea* genus are used, namely, *E. purpurea*, *E. angustifolia*, and *E. pallida* in the treatment of upper respiratory tract infections [103]. Echinacea products contain alkylamides that are known to modulate CYP activity, in particular, CYP1A2 and CYP3A4 [104]. However, the type and concentration of the alkylamide present can vary depending on the *Echinacea* species [105]. This is perhaps the cause for the conflicting reports in the literature regarding the effect of Echinacea products on CYP activity *in vivo* [76,80].

Coadministration of Echinacea has been reported to either decrease the clearance of caffeine as reported by Gorski *et al.* [104] or have no effect on the PK of caffeine as reported by Gurley *et al.* [76]. A potential mechanism suggested for the lower clearance of caffeine is the inhibition of CYP1A2 by Echinacea. In this study, slight inhibition of CYP2C19 was also observed; however, the extent of inhibition was considered to be clinically insignificant [104]. Similarly, these two clinical studies also reported different outcome on the effect of Echinacea on CYP3A4. Gorski *et al.* reported increased systemic clearance of midazolam associated with increased oral bioavailability of midazolam suggesting inhibition of intestinal CYP3A4 and induction of hepatic CYP3A4 [104], whereas Gurley *et al.* reported no effect on CYP3A4 activity [76]. Also, the PK of digoxin, a P-gp substrate, was unaffected after administration of Echinacea [106]. Thus, currently, there are no clinical case reports that point to serious safety-impacting interactions of this herb with other drugs.

19.6.10 Evening Primrose Oil (*Oenothera biennis*, Family Onagraceae)

Evening primrose oil (EPO) is an oil that is extracted from the flowers of *Oenothera biennis* and is rich in linoleic acid and γ -linolenic acid (GLA), a polyunsaturated fatty acid [107]. EPO is generally used for the treatment of allergy-induced eczema, premenstrual syndrome, breast pain and tenderness, diabetic neuropathy, rheumatoid arthritis, and osteoporosis [108,109]. There are no published literature reports on interactions of EPO with other drugs.

19.6.11 Garlic (*Allium sativum*, Family Liliaceae)

Garlic, which is a common herb used in various cuisines, is also used in the reduction of hypertension and hyperlipidemia including prevention of arteriosclerosis [110]. It is also thought to possess some immune system strengthening and antimicrobial effect [111,112], which makes it the herb of choice in HIV-infected patients [113]. There are many known active ingredients in garlic cloves; however, the organosulfur compounds, such as allicin, alliin, *S*-allylcysteine, *S*-allylmercaptocysteine, diallyl sulfide, dipropyl sulfide, and dipropyl disulfide, are believed to be the therapeutic ingredients [114–117].

Case studies have been reported in the literature implicating interactions with garlic and other drugs such as anticoagulants, antiretrovirals, hypoglycemic, and analgesics.

Administration of garlic capsules twice daily for 14 days to normal healthy volunteers did not alter the PK of probe substrates that are metabolized by CYP3A4 such as midazolam [118] and alprazolam [119] or of dextromethorphan [119] which is metabolized by CYP2D6. However, garlic inhibited CYP2E1, as determined by the assessment of PK of the CYP2E1-selective probe substrate, chlorzoxazone [67].

After administration of garlic orally for three weeks to healthy volunteers, a twofold decrease in the plasma exposure of the coadministered HIV protease inhibitor, saquinavir, was observed [120]. This was hypothesized to be due to decreased bioavailability of saquinavir, which could be a result of P-gp inhibition, as saquinavir is a known substrate of CYP3A4 [121] and P-gp [122], and it has been shown that garlic does not modulate the *in vivo* activity of CYP3A4 using midazolam [118] and alprazolam [119] as probes, as discussed earlier. In fact, it was later shown that raw garlic and garlic products cause slight to moderate inhibition of P-gp *in vitro* [123], although the inhibition was not as strong compared to verapamil, a potent P-gp inhibitor. However, in a separate study reported by Gallicano *et al.* [124], single-dose PK of ritonavir, another HIV protease inhibitor, was unaltered after consecutive daily dosing of garlic for four days. It is postulated that a longer duration of dosing for garlic might contribute to alteration of ritonavir PK. In contrast, Laroche *et al.* [125] reported severe gastrointestinal toxicity for two HIV-infected patients who were taking garlic capsules for a little over two weeks before beginning ritonavir (400 or 600 mg, bid) treatment. This toxicity was attributed to the coadministration of garlic and ritonavir as it was found to be reversible when either drug was discontinued and recurred when a lower dose of ritonavir (100 mg) was coadministered with garlic. Although the underlying mechanism for the interaction between garlic and ritonavir needs to be further investigated, it has been postulated that either ritonavir modulates the metabolism of garlic leading to production of toxic metabolites or the garlic constituents might inhibit the CYP3A4-based metabolism [126] or P-gp-mediated transport of ritonavir [125], thereby leading to increased ritonavir concentrations. It is also possible, given that ritonavir autoinduces its metabolism during the first two weeks of therapy [127], that the effect of concomitantly administered garlic may be more pronounced after a single dose of ritonavir as compared to after multiple doses. Studies conducted with garlic products or the known active ingredients have shown some potential for interaction with P-gp as well as inhibition of cDNA-expressed CYP enzymes *in vitro* [123].

Interaction with docetaxel, a CYP3A4 substrate, was assessed clinically in women with metastatic breast cancer receiving docetaxel weekly for three weeks [128]. Three days after the initial dose of docetaxel, patients received 600 mg of garlic twice daily for 12 consecutive days. Docetaxel PK was assessed after each dose, and it was found that garlic did not significantly affect the disposition of docetaxel. However, there was some potential that garlic decreased the clearance of docetaxel in patients carrying a CYP3A5*1A allele.

Following a three-month dosing of garlic extract, assessment of acetaminophen PK showed a slight increase in sulfation of acetaminophen, however, did not alter the extent of oxidative and glucuronidation metabolites [129]. Overall, the authors concluded that garlic did not affect the PK of acetaminophen. In addition, diallyl sulfone has

been shown to inhibit the oxidation of acetaminophen to its hepatotoxic metabolite, *N*-acetyl-*p*-benzoquinone imine, in human liver microsomes [130].

PD-based herb–drug interactions have also been reported for garlic with anticoagulants and antihyperglycemic agents. *In vitro* and *in vivo* studies conducted with certain organosulfur compounds present in garlic have demonstrated that garlic inhibits platelet aggregation in humans [131–134]. There are case reports of postoperative bleeding [135,136] and spontaneous spinal epidural hematoma that are considered to be linked to ingestion of garlic products [137,138]. Thus, the anticoagulant effect of garlic is responsible for increased clotting time and INR after concomitant dosing of garlic and warfarin [139–142]. Similarly, garlic extracts have been shown to produce antihyperglycemic effects in animals [143–145] and humans [146,147]. A literature report [148] described that the concomitant administration of chlorpropamide (which is used to treat diabetes), garlic, and bitter melon led to enhanced hypoglycemic response. This is another example of a PD herb–drug interaction, as each by itself exhibits antihyperglycemic properties.

19.6.12 Ginger (*Zingiber officinale*, Family Zingiberaceae)

Ginger is a commonly used botanical in many culinary preparations and is most commonly used as a household remedy for nausea, especially during the first trimester of pregnancy [149]. It is also reported to have antiemetic property including treatment of gastrointestinal infectious diseases, anti-inflammatory, and antiplatelet activity [150].

There are no reported clinical studies that have assessed the potential for its interaction with other drugs via CYP- or P-gp-related mechanism. On the basis of its pharmacological properties, Jiang *et al.* [151] assessed its potential to cause bleeding when coadministered with warfarin and reported no alteration in warfarin PK or in the coagulation parameters after administration of ginger.

19.6.13 Ginkgo (*Ginkgo biloba*, Family Ginkgoaceae)

The leaves of *Ginkgo biloba* contain powerful antioxidants and are mainly used for improving memory and for cerebral insufficiency and peripheral vascular disease [103,152]. The known active constituents, ginkgolide and bilobalide, have been shown to function as antagonists of the platelet-activating factor (PAF) receptor and therefore have antiplatelet aggregation activity [153].

In vitro study with cDNA-expressed CYPs has shown that the ginkgolic acids present in ginkgo biloba were potent inhibitors of CYP1A2, CYP2C9, and CYP2C19 with IC₅₀ values ranging from 2.41 to 4.88 μ M [154]. Ginkgo also moderately inhibited CYP2C8 [155], CYP2C9 [156], and CYP3A4 [157] *in vitro* in human liver microsomes; however, the studies reported in the literature to determine the potential of *Ginkgo* to inhibit CYP2C19 and CYP2D6 present conflicting results [154,158–160].

In contrast to the moderate (apparent K_i of 14.8 μ M) inhibition of CYP2C9 observed *in vitro* in human liver microsomes [156], ginkgo did not show any potential for interaction with CYP2C9 probe substrates, as evidenced by unaltered steady-state PK of diclofenac or on the urinary metabolic ratio of tolbutamide [156]. Consistent with this *in vivo* finding, the PK of another CYP2C9 substrate, flurbiprofen, was also unaffected by ginkgo [161].

There was a case report of elevated levels of antiepileptic drugs, valproic acid and phenytoin, in a 55-year-old man taking ginkgo in addition to herbs, and since the common CYP that metabolized both is CYP2C19, inhibition of CYP2C19 by ginkgo is suggested as the underlying reason [162]. Yin *et al.* [163] conducted a clinical study to look at effects of ginkgo treatment on the PK of omeprazole and hydroxylation of omeprazole. They reported a significant decrease in the ratio of AUC of the parent to AUC of its hydroxylated metabolite, with the decrease being higher in a poor metabolizer than an extensive metabolizer with regard to CYP2C19 genotype, thus indicating that ginkgo induced CYP2C19.

Smith *et al.* [66] reported a clinical study in healthy volunteers to assess the effect of ginkgo on the PK of nifedipine, a CYP3A4 substrate. A 53% increase in the peak plasma concentration of nifedipine at 30 min postdose was reported in this study, suggesting inhibition of CYP3A4. In contrast, another clinical study reported later by Yoshioka *et al.* [164] showed that ginkgo did not alter nifedipine PK. In addition, Markowitz *et al.* [165] reported a clinical study to assess the effect of ginkgo on CYP3A4 using alprazolam as a CYP3A4 substrate and CYP2D6 using dextromethorphan as a substrate. The data indicated that administration of ginkgo had no effect on both these CYP isozymes. A similar outcome for CYP3A4 was observed in a separate study reported by Yasui-Furukori *et al.* [166]. In this study, ginkgo extract was administered once daily for 30 days to 14 patients undergoing treatment with donepezil, a cholinesterase inhibitor, for Alzheimer's disease. Neither the plasma concentration of donepezil, which is metabolized by CYP3A4 and CYP2D6 [167], nor the cholinesterase activity in the red blood cell or the cognitive function of the patients over the duration of the study was significantly altered by ginkgo. In addition, a few other studies to clinically evaluate the effect of ginkgo on CYP3A4 are reported below. Robertson *et al.* [168] reported that ginkgo did not significantly alter the PK of antiretrovirals (lopinavir and ritonavir); however, it was observed that the AUC of midazolam decreased, suggesting induction of CYP3A metabolism. Uchida *et al.* [169] reported that ginkgo inhibited CYP3A metabolism resulting in increased AUC of midazolam and induction of CYP2C9 as evidenced by the decrease in AUC of tolbutamide. Additional studies are needed to elucidate the induction or inhibition effects of ginkgo on CYP3A metabolism since the existing reports in the literature are conflicting.

Similarly, assessment of the potential of ginkgo to cause P-gp-related interaction with drugs that are P-gp substrates gave mixed results when studied using digoxin and talinolol as P-gp probes. Ginkgo did not cause any significant alteration of digoxin PK [170], while it significantly increased the bioavailability of talinolol [171]. Therefore, similar to CYP3A4, the clinical potential for ginkgo to cause herb-drug interactions due to P-gp-related mechanism needs to be investigated further.

Several clinical reports of hemorrhage have implicated ginkgo either postoperatively [172–175] or when taken concomitantly with drugs that have anticoagulant activity such as warfarin [176,177] or clopidogrel [178] and nonsteroidal anti-inflammatory agents such as ibuprofen, aspirin, and rofecoxib [179]. Since, ginkgo does not seem to modulate any of the CYP activities to produce metabolism-based interactions with other drugs based on PK of known probe drugs for various CYP enzymes [156,180–182], the underlying mechanism for these case reports appears to be PD-based rather than metabolism related. However, the outcome of a prospectively designed repeat-dose (14 days) clinical study that was randomized, double-blind, and placebo-controlled in

young healthy male volunteers was that the administration of an extract of ginkgo does not cause significant changes in blood coagulation parameters [183]. Similarly, another study evaluated the effect of coadministration of ginkgo and acetylsalicylic acid on blood coagulation parameters and demonstrated that ginkgo did not produce any additional effect on bleeding time or other coagulation parameters [184].

Other sporadic reports of clinical interactions of ginkgo with other drugs, such as antihyperglycemic metformin [185] or antipsychotic risperidone [186] and antidepressant trazodone [187,188], are available and these are thought to be PDs based and hence are not discussed here.

19.6.14 Green Tea (*Camellia sinensis*, Family Theaceae)

Green tea is a popular beverage and is also available in the form of capsules containing concentrated extract. It is commonly recognized as an antioxidant and has been shown to have anti-inflammatory [189] and antineoplastic properties [190] and is often used as a prophylactic for cancer [191] as well as to aid weight loss [192,193]. There are several catechins in green tea extract which are active ingredients, of which the most abundant is epigallocatechin gallate and its recommended daily dose for therapeutic effect is 100–750 mg [194,195].

Green tea was shown to strongly inhibit CYP2C9, CYP2D6, and CYP3A4 activities in human liver microsomes using tolbutamide, bufuralol, and testosterone as probe substrates [196]. Also, Mirkov *et al.* [195] demonstrated that the catechins from green tea inhibited the CYP3A4-catalyzed oxidation of irinotecan and UGT1A1-catalyzed conjugation of its metabolite, SN-38, in human liver microsomes; however, they did not induce CYP3A4 in human hepatocytes.

In contrast to the *in vitro* studies, a clinical study conducted by Donovan *et al.* [197] to assess the effect of decaffeinated green tea on CYP2D6 and CYP3A4 showed no potential for herb–drug interaction via these two isozymes. In a later study conducted by Chow *et al.* [198] using a similar dose but with a longer duration (4 weeks vs 14 days in the prior study), it was observed that there was no effect on the activities of CYP1A2, CYP2C9, CYP2D6, or CYP3A4, although there was a slight inhibition of CYP3A4 activity as evident from an increase in buspirone AUC, however, it was considered to be clinically insignificant.

19.6.15 Kava (*Piper methysticum*, Family Piperaceae)

Kava (roots and rhizome) is used as an anxiolytic [103]. There have been numerous clinical cases of hepatotoxicity with coadministration of kava with other drugs [199].

Clinical studies with specific probe substrates have shown that kava inhibits CYP2E1 [79]; however, no effect was found on other CYPs such as CYP1A2, CYP2D6, and CYP3A4 [79,200]. A separate clinical study conducted by Gurley *et al.* [201] showed no significant alteration in digoxin PK due to coadministration of kava, due to which there does not appear to be any potential for clinical interaction of kava with other drugs that are P-gp substrates.

Clinical lack of efficacy has been reported for levodopa used to treat Parkinson's disease [202]. Serious adverse effect of being in a semi-comatose state has been reported for concurrent use of benzodiazepine alprazolam [203], while concomitant use of paroxetine to treat depression led to a lethargic state with diffuse muscular weakness and

some cognitive difficulty [204]. However, these interactions are thought to be PD in nature due to the direct effect of kava at dopamine and GABA receptors [205] rather than metabolism dependent.

19.6.16 Licorice (*Glycyrrhiza glabra*, Family Leguminosae)

The root of licorice has traditionally been used to treat sore throat and has recently been clinically shown to be effective [206]. It is a commonly used herb used in Chinese and Japanese traditional medicine. Licorice is also recognized as a natural sweetener, since the active ingredient, glycyrrhizin or glycyrrhizic acid, is 50 times sweeter than sugar [207,208].

In vitro studies conducted with expressed human P4503A4, 2B6, and 2C9 and glabridin, an isoflavone present in licorice, demonstrated time- and concentration-dependent inactivation of CYP2B6 and CYP3A4, while CYP2C9 was competitively inhibited [209]. Another *in vitro* study conducted by Budzinski *et al.* [210] in human liver microsomes with an extract of licorice showed that CYP3A4-mediated metabolism of benzyloxyresorufin was inhibited. However, Shon *et al.* [211] observed no significant change in the PK of midazolam in healthy volunteers who were given licorice extract for seven days, indicating that licorice does not show the potential for interaction with drugs that are substrates for CYP3A4. Thus, the nonconcordance of *in vitro* data to clinical studies could presumably be due to the different sources of the herb in these studies that could presumably have led to varying chemical composition.

There have been clinical reports of life-threatening hypokalemic paralysis reported in association with long-term licorice consumption [212,213]. It is unclear whether the hypokalemic paralysis is related to the inhibition of 5 α -, 5 β -reductase and 11 β -dehydrogenase which *in vitro* studies have shown glycyrrhizin and glycyrrhetic acid to be potent inhibitors of [214,215]. These enzymes play a role in steroid metabolism; hence, the *in vitro* inhibition studies suggest that the decreased steroid metabolism could potentiate the effect of endogenous and administered steroids [216]. Homma *et al.* [217] evaluated the effect of three Chinese herbal products, containing equal amounts of glycyrrhizin, on prednisolone PK and also measured the ratio of AUC of prednisone to AUC of prednisolone which is an indicator of 11 β -hydroxysteroid dehydrogenase activity. In this study, a significant increase (15.2%) in plasma prednisolone AUC was observed with one of the herbal preparation with a corresponding decrease in the ratio, while a significant decrease (17.2%) in prednisolone AUC was observed on coadministration of another herbal product with a corresponding increase in the ratio. Coadministration with the third product did not significantly alter the prednisolone plasma AUC or the ratio. This difference could be due to the presence of other components in the herbal product that could have different effects on steroid metabolism. These studies, taken as a whole, emphasize the challenges faced in assessing herb–drug interactions.

19.6.17 Milk Thistle (*Silybum marianum*, Family Asteraceae)

The extract of the seeds of *Silybum marianum* has been reported to have a hepatoprotective effect and is often used to reverse drug-mediated hepatotoxicity [218]. It is often used by patients diagnosed with viral hepatitis [219]. A typical extract of milk

thistle contains ~4–6% silymarin, which is considered to be the primary active ingredient, about 65–80% silymarin (a flavanolignan complex), and 20–35% fatty acids, including linoleic acid [220].

Several studies have been reported with drugs such as aminopyrine [221], irinotecan [222], indinavir [223–225], metronidazole [226], nifedipine [227], phenylbutazone [221], ranitidine [228], and rosuvastatin [229] as well as with standard probe substrates [118] such as caffeine (CYP1A2), debrisoquin (CYP2D6) [230], chlorzoxazone (CYP2E1), and midazolam (CYP3A4) [231], which assessed the effect on the activity of various CYP isozymes after daily dosing with milk thistle for 7, 14, 17, 21, or 28 days and observed no significant impact. There was a minor reduction in the AUC of indinavir in the two clinical studies reported by Piscitelli *et al.* [223] and by DiCenzo *et al.* [224]; however, it was considered to be clinically insignificant for indinavir. Consistent with these results, another active ingredient, silibinin, was reported to have no effect on the isozyme activity *in vitro* in human liver microsomes when evaluated by Beckmann-Knopp *et al.* [232] using erythromycin (CYP3A4), chlorzoxazone (CYP2E1), S(+)-mephenytoin (CYP2C19), caffeine (CYP1A2), or coumarin (CYP2A6) as probe substrates. However, Venkataramanan *et al.* [233] reported that silymarin at a high concentration of 0.1–0.25 mmol/L, significantly decreased CYP3A4-mediated 6 β -hydroxylation of testosterone as well as glucuronyltransferase activity in human hepatocytes. Sridar *et al.* [234] have reported that silibinin is a mechanism-based inhibitor of CYP3A4 and CYP2C9. These studies indicate that a systematic assessment is important to be able to predict interaction of milk thistle with drugs metabolized by CYP2C9, CYP2D6, CYP2E1, or CYP3A4.

Milk thistle did not alter digoxin PK *in vivo* indicating that it did not inhibit P-gp [82]. However, in contrast, a decrease in serum metronidazole concentrations was observed and it was attributed to an upregulation of P-gp [226]. In addition, *in vitro* studies with silymarin demonstrated increased accumulation of daunorubicin in cells expressing P-gp phenotype compared to cells that did not express P-gp, and photoaffinity labeling showed a direct interaction with P-gp binding [235]. Similarly, the cytotoxic effects of doxorubicin were potentiated *in vitro* by silibinin [236] and high affinity labeling to P-gp was inferred to be the cause [237]. Thus, the literature reports of significant modulation of P-gp by the active constituents silymarin and silibinin show the potential for clinical interaction of milk thistle with other P-gp substrates. Therefore, additional studies are required to understand the impact of milk thistle treatment on P-gp.

19.6.18 Saw Palmetto (*Serenoa repens*, Family *Arecacea/Palmae*)

Dried ripe fruits of Saw Palmetto are widely used for the treatment of stages I and II of benign prostatic hyperplasia [238]. Fatty acids, flavanoids, and plant sterols are the active ingredients in saw palmetto [239]. No serious clinical side-effects have been reported in patients taking saw palmetto [240].

Yale and Glurich reported potent inhibition of cDNA-expressed human P450C9, 2D6, and 3A4 by saw palmetto [241]. In contrast to these data, two independent clinical studies conducted in healthy volunteers by Gurley *et al.* [118] and Markowitz *et al.* [242], with selective CYP substrates for CYP1A2, CYP2D6, CYP2E1, or CYP3A4, showed no significant potential for herb–drug interactions mediated through these CYPs.

19.6.19 Siberian Ginseng (*Eleuthrococcus senticosus*, Family Araliaceae)

The roots of Siberian ginseng have immunomodulatory properties and are used as an adaptogen to confer resistance to the effects of stress [243]. The major pharmacological constituents of Siberian ginseng are the eleutherosides.

The effect of Siberian ginseng on CYP2D6 and CYP3A4 activities was assessed after daily dosing for 14 days using dextromethorphan and alprazolam as probe substrates, respectively [244]. No significant change in the PK of both these probes was observed in this study. This was consistent with the results of the *in vitro* study using cDNA-expressed human CYP3A4 where the extract of Siberian ginseng did not inhibit CYP3A4 [210]. A case report of increased serum digoxin concentrations without any signs of toxicity in a patient taking Siberian ginseng was investigated further [245]. It appeared that Siberian ginseng contained some digoxinlike entities that posed interference in the serum digoxin assay and ruled out involvement of P-gp interaction [246].

19.6.20 St. John's Wort (*Hypericum perforatum*, Family Hypericaceae)

SJW is a very popular herb used in the treatment of mild, moderate, and major depression [247,248], which is typically used in a chronic setting. Two major classes of biologically active compounds include the hypericins which are anthraquinones with antiviral and anticancer activity and the hyperforins which are prenylated acylphloroglucinols which display potent antimicrobial activity and are thought to be the primary bioactive ingredient for antidepressive effects of the herb [249].

When used as a monotherapy, treatment with SJW is quite safe. However, there are several clinical reports of adverse effects on concomitant administration of SJW with different drugs as a result of PK-based interaction due to either or both induction of CYP and intestinal P-gp which have been reviewed by Zhou and Lai [250]. This review cites studies reporting interactions with anticancer agents, anti-inflammatory drugs, antimicrobials, antiretrovirals, cardiovascular drugs, CNS drugs, contraceptives, hypoglycemic, immunosuppressants, and drugs acting on the respiratory system. The interaction of SJW with other drugs was observed ~14 days after daily administration of SJW; studies conducted after acute administration of SJW showed no potential for interaction, thereby suggesting that induction of CYP enzymes and/or P-gp could be the underlying mechanism [251–253].

Several clinical reports and clinical studies with SJW have confirmed the ability of SJW to induce CYP3A4, CYP2C19, and CYP2E1, and/or P-gp with no effect on activities of CYP1A2, CYP2C9, or the noninducible CYP2D6 [254–260]. Typically, the observed enzyme induction is reversible one week after cessation of SJW treatment [261]. It has been demonstrated that SJW extract and hyperforin treatment of primary human hepatocytes causes induction of CYP3A4 via the activation of PXR [262,263].

The interaction of SJW with P-gp substrates was evident from the lowered plasma concentrations of well-known P-gp substrates including digoxin [47,106,264] and fexofenadine [265,266]. Decreased plasma concentrations have also been observed for talinolol, another clinical probe for P-gp, when administered after pretreatment with SJW [267]. These talinolol PK data combined with a corresponding increase in MDR1 mRNA as well as protein levels of P-gp in the intestinal mucosa in humans, reported in the same study, indicate that SJW induces P-gp [267]. It is also believed that the hypericin in SJW is responsible for the induction of P-gp [264].

The use of SJW is very common in patients who have undergone organ transplant procedure and are undergoing treatment with an immunosuppressant such as cyclosporine or tacrolimus, since these patients also tend to experience depression. The interaction of SJW and cyclosporine has been the most well documented with reports of patients transplanted with heart, liver, or kidney and stabilized on cyclosporine showing acute rejection of the transplanted tissue which was associated with decrease in plasma cyclosporine level, after taking SJW at therapeutic doses [268]. Improvement was observed in most patients after discontinuation of SJW. Mai *et al.* [269] reported that after dosing stable renal transplant patients with SJW, a decrease in tacrolimus concentration but not of mycophenolic acid was observed, thereby confirming that induction of CYP3A4 and P-gp is responsible for the increased drug clearance, since tacrolimus is a substrate for both P-gp and CYP3A4, while mycophenolic acid is primarily metabolized by glucuronidation.

Patients on antineoplastic therapy also tend to self-medicate with SJW. Two independent clinical trials in healthy volunteers have been reported with SJW and two anticancer agents, imatinib [270,271] and irinotecan [272]. Imatinib is a potent inhibitor of Bcr-abl and c-kit tyrosine kinase and is mainly metabolized by CYP3A4 and is a P-gp substrate, while SN-38 is the active metabolite of irinotecan which is a CYP3A4 substrate. In both these studies, decreased plasma concentration of the anticancer agent, imatinib, or the active metabolite of irinotecan, SN-38, was reported after pretreatment with SJW.

Failure of anti-HIV therapy has been observed with antiretrovirals such as indinavir [273] and nevirapine [274], which are both CYP3A4 substrates. Decrease in the plasma concentration of the protease inhibitor, indinavir, was observed in healthy volunteers dosed with SJW for 14 days in an open-label trial that is attributed to the induction of CYP3A4. The nonnucleoside analog, nevirapine, which is metabolized by CYP3A4 and CYP2D6, showed increased oral clearance in five HIV-infected patients, when SJW was coadministered suggesting induction of CYP3A4. HIV viral load, as determined from the measurement of HIV mRNA, was also significantly increased in a patient after he took SJW concomitantly with indinavir and lamivudine [275]. It is postulated that the reported interaction between SJW and the antiretrovirals was due to the induction of CYP3A4 by SJW.

Induction of CYP3A4 has also caused failure of therapy for several cardiovascular drugs which are metabolized by CYP3A4 to a significant extent such that the autoinduction leads to a decrease in the serum concentration of these drugs making them less effective. These include the calcium channel blockers nifedipine [276] and verapamil [277], and the antihyperlipidemic drugs, atorvastatin [278], and simvastatin [279] but not pravastatin [279] which is not a substrate for CYP3A4 or for P-gp. In addition, clinical cases of increase in coagulation parameters when taking anticoagulants such as warfarin (racemic mixture of *R*- and *S*-enantiomers) have been reported, and it is documented that while *S*-warfarin is metabolized by CYP2C9, the *R*-enantiomer is metabolized by CYP1A1 and CYP3A4 [280].

SJW has been shown to increase the clearance of contraceptives such as ethinylestradiol, norethindrone, and ketodesogestrel, which was attributed to the induction of CYP3A4 as these drugs are substrates for CYP3A4 [281–283].

Hypoglycemic drugs such as tolbutamide is metabolized predominantly by CYP2C9 and its coadministration with SJW did not alter its PK [284], suggesting that SJW does not modulate CYP2C9 activity. In contrast, the PK of gliclazide, another CYP2C9

substrate used in the treatment of diabetes, was significantly altered by SJW in the absence of any significant change in CYP2C9 genotype [285], thus suggesting that the mechanism was independent of CYP2C9.

SJW has been shown to reduce plasma concentrations of fexofenadine, a long-acting antihistaminic drug, which is used as a P-gp substrate [265,266].

Plasma levels of voriconazole, an antifungal agent and CYP2C19 substrate, decreased after long-term coadministration of SJW in a clinical study [252]. This observation supports the enzymatic induction of CYP2C19.

Clinical study that involved coadministration of omeprazole with SJW over a period of 2 weeks resulted in decreased plasma concentrations of omeprazole and increased concentration of metabolites, CYP3A4-mediated sulfoxidation, and 2C19-catalyzed hydroxylation, indicating induction of both these CYP enzymes by SJW [286].

19.6.21 Valerian (*Valeriana officinalis*, Family Valerianaceae)

The extract of dried roots of valerian has been historically used to treat insomnia as an alternative to benzodiazepine and sometimes as an anxiolytic, hypnotic, and anticonvulsant [287,288]. It is sometimes also used in the treatment of migraine due to claims of its muscle relaxant property as well as in the treatment of gastrointestinal cramps and irritable bowel syndrome. The primary chemical components of valerian are valerenic acid and its derivatives, valepotriates, alkaloids, furanofuran lignans, and free amino acids [289].

Organic extracts of the valerian root have shown inhibition of CYP3A4 *in vitro* up to 88% [290], whereas valerenic acid, an active component in valerian, has demonstrated a much lower inhibitory potential toward CYP3A4 and minor inhibition of CYP2C9 and CYP2C19 [291]. Donovan *et al.* [292] evaluated the effect of valerian extract dosed at 1000 mg/day for 16 days and observed minimal alteration of CYP3A4 activity that was not clinically significant and no effect on CYP2D6. Gurley *et al.* [79] reported that dosing valerian at a total daily dose of 375 mg for 28 days had no impact on CYP1A2, CYP2D6, CYP2E1, and CYP3A4. While there are no literature reports of the potential for valerian to interact with P-gp substrates, no clinical reports of adverse events linked to valerian are currently available.

19.7 CONCLUSIONS AND FUTURE PERSPECTIVES

It is estimated that ~30% of patients in the United States currently use herbal dietary supplements [293]. Similarly, in other developed countries such as Australia, New Zealand, and some of the European countries, an estimated one third of adults use herbal supplements for promoting health and managing diseases [294]. The proportion of adults using herbal remedies increases sharply in many developing countries such as China and India, where more than 80% of the population is known to use herbal products [294]. Reasons for the increased use of herbal products include the popular belief that remedies of natural origin are safe, affordable, and easily available (i.e., local health foods, neighborhood grocery stores, and discount supermarkets) [295]. Many patients while taking herbal dietary supplements do not inform their physicians and a reason cited for this lack of communication may be fear of disapproval by their physicians or a desire to control personal therapy [296]. An important and real

safety concern associated with the use of herbal dietary supplements is that the ADME properties are rarely known, leading to an increased risk of unexpected interactions when concomitantly administered with prescription medications. The PK interactions of prescription medications by herbs that have been reported are primarily associated with inhibition or induction of CYP and P-gp enzymes; however, in many cases, the *in vitro* data do not accurately predict the clinical outcome. Thus, further studies are necessary to be able to develop a predictive assessment for clinical herb–drug interactions.

Currently, a knowledge gap exists with the interaction of prescription medication on the PK and PD of herbs and herbal formulations. With the cost of prescription medications skyrocketing and an increased health-awareness in the general population, it is inevitable that the use of herbal dietary supplements will increase. It is the need of the hour, therefore, that studies are conducted with scientific rigor and acceptable norms to characterize herbal medicines with regulatory oversight, much like is done today with pharmaceutical drugs.

ABBREVIATIONS

AUC	Area Under the Concentration Curve
$C_{\max}$	Maximum Concentration
CYP	Cytochrome P450
EMA	European Medicines Agency
FDA	Food and Drug Administration
P-gp	P-glycoprotein
$T_{\max}$	Time Required to Reach $C_{\max}$
$t_{1/2}$	Half-Life
UGT	Uridine Glucuronosyltransferase

20 ADME of Anticancer Drugs

HIROSHI YAMAZAKI

Showa Pharmaceutical University, Machida, Tokyo, Japan

20.1	Summary	1
20.2	Tegafur and CYP2A6	2
20.3	Letrozole and CYP2A6	3
20.4	Tamoxifen and CYP2D6	4
20.5	Thalidomide and CYP3A4/5	6
20.6	Irinotecan and UDP-glucuronosyltransferase 1A1	7
20.7	6-Mercaptopurine and thiopurine-S-methyltransferase	8
20.8	Carboplatin and hyperbaric oxygenation	8
20.9	Conclusions	9
	References	10

20.1 SUMMARY

Cytochrome P450 (P450 or CYP) comprises a superfamily of heme-thiolate monooxygenases involved in the oxidation of a large number of endogenous and exogenous compounds [1]. In human liver, CYP3A4 is the major P450 enzyme, followed by CYP2C9 [2]. An important role for polymorphic CYP3A5 in drug oxidation in African and Asian populations has been suggested [3,4]. CYP2D6 and CYP2C19 also catalyze the oxidation of many marketed drugs [5], but their content in human liver is relatively low [6]. Recently, CYP3A enzymes have been identified as being involved in the biotransformation of many anticancer drugs, as shown in Table 20.1. Large interindividual variations in the contents and activities of several P450 forms in human livers lead to different roles of P450s in the oxidations of substrates associated with pharmacological or toxicological actions [1].

Pharmacogenetics is a rapidly developing field, especially in oncology. In an ideal future scenario, pharmacogenetics will allow oncologists to personalize therapy based on patients' individual germline genetic test results. This would help improve efficacy, reduce toxicity, and predict nonresponders in a way that would allow an alternative approach to be chosen or individual dose adjustments to be made. Multiple pathways of drug metabolism have been studied extensively, for example, variations in the *UGT1A* gene and the *ABCC2* gene influence irinotecan metabolism and disposition [7]. Other genetic changes result in reduced DNA repair capacity related to platinum efficacy

TABLE 20.1 Drug-Metabolizing Enzymes Involved in Biotransformation of Anticancer Drugs

Drug-Metabolizing Enzymes	Anticancer Drugs
P450 2A6	Anastrozole, fadrozole, letrozole, tegafur
P450 2B6	Cyclophosphamide, ifosfamide
P450 2C8	Paclitaxel
P450 2D6	Tamoxifen
P450 3A4	Cyclophosphamide, docetaxel, etoposide, gefitinib, ifosfamide, imatinib, irinotecan, retinoic acid, tamoxifen, teniposide, vinca alkaloids
UGT1A1	Irinotecan
DPYD	5-Fluorouracil
TPMT	Azathioprine, mercaptopurine

or reduced cytochrome CYP2D6 activity related to tamoxifen efficacy. Despite the extensive number of pharmacogenetic studies and their promising results, it is still unclear when and how pretreatment genetic screening will be implemented in oncology. Future prospective studies should focus on the effects of pharmacogenetics on patient outcome and then combine this with evaluations of cost effectiveness. In this section, recent findings on anticancer drug metabolism are summarized.

20.2 TEGAFUR AND CYP2A6

Tegafur [5-fluoro-1-(2-tetrahydrofuryl)-2,4(1*H*, 3*H*)-pyrimidinedione], an anticancer prodrug of 5-fluorouracil (5-FU), has been used clinically for over 30 years for chemotherapy [8]. It has been reported that tegafur is bioactivated to 5-FU (Fig. 20.1) mainly in the liver and that 5-FU may inhibit the growth of cancer cells by the inhibition of thymidylate synthase or by its incorporation into RNA [9]. 5-FU is further biotransformed to an inactive molecule by dihydropyrimidine dehydrogenase (DPYD) in the liver cytosol [10]. Two pathways have been proposed for the conversion of tegafur to 5-FU, the major pathway occurring in the microsomal fraction and the minor pathway in the cytosolic fraction [11]. Liver microsomal 5-FU formation from tegafur is catalyzed by the phase I drug-metabolizing enzymes CYP2A6, CYP1A2, and CYP2C8 [12,13]. On the other hand, cytosolic 5-FU formation from

**Figure 20.1** Tegafur and its metabolite, 5-fluorouracil.

tegafur is thought to be catalyzed by thymidine phosphorylase [14]. Thymidine phosphorylase, purified from human gastric tumor tissues, has been shown to catalyze 5-FU formation from tegafur as well as thymine formation from thymidine [15]. Thymidine phosphorylase levels were reported to be higher in various tumor tissues than in normal tissues [16]; therefore, 5-FU formation from tegafur in tumor tissues is considered to be mainly catalyzed by thymidine phosphorylase. The involvement of human liver microsomes and cytosol in 5-FU formation from tegafur in the presence of 5-chloro-2,4-dihydropyridine, a DPYD inhibitor, has been reported [17]. Moreover, it was confirmed that cytosolic 5-FU formation is mainly catalyzed by thymidine phosphorylase, not by uridine phosphorylase.

Tegafur has been clinically used for the treatment of various cancers. Recently, it has been used in combination with modulators such as 5-chloro-2,4-dihydropyrimidine (CDHP) and potassium otastat [18]. Many enzymes are known to be involved in the metabolism of tegafur, although P450 and dihydropyrimidine dehydrogenase are rate-limiting enzymes activating tegafur to 5-FU and inactivating 5-FU, respectively [10,19].

If a cancer patient lacks CYP2A6 activity, the patient is expected to have a poor metabolic phenotype in terms of the efficacy of tegafur. In a clinical study, a newly developed anticancer drug, TS-1 capsules, containing tegafur and CDHP, an inhibitor of DPYD, were orally administered to several gastric cancer patients [20]. The total area under the plasma tegafur concentration–time curve (AUC) in one patient was fourfold higher than that for the other patients. From this subject, a novel CYP2A6 mutation was found that causes an amino acid change from serine to proline at residue 224 [20]. It was concluded that the poor metabolic phenotype of this patient was caused by the existence of two mutant alleles: *CYP2A6*4* (whole deletion of *CYP2A6*) and a new variant, *CYP2A6*11* [20].

20.3 LETROZOLE AND CYP2A6

Aromatase inhibitors directed toward CYP19A1 are a good alternative to anti-estrogens in the treatment of hormone-dependent breast cancer. Aromatase (or CYP19A1) is the enzyme responsible for the rate-limiting step in estrogen synthesis and it is by inhibiting CYP19A1, and as a consequence inhibiting estrogen formation, that aromatase inhibitors present pharmacological activity [21]. The aromatase inhibitors used today, that is, anastrozole, letrozole (4,4'-[1*H*-1,2,4-triazol-1-ylmethylene]bis-benzonitrile, Fig. 20.2), and exemestane, are third-generation drugs, all having high specificity for the aromatase enzyme [22].

Letrozole is an orally active, nonsteroidal competitive inhibitor of aromatase [23] or CYP19A1. CYP19A1 catalyzes the three-step oxidation of androgens to estrogens [24], and its expression is known to be relevant to estrogen-dependent tumors [25]. Although letrozole is currently used worldwide for treatment of advanced breast cancer in postmenopausal women [26], knowledge is still limited regarding the roles of different P450 isoforms, including the pharmacological target site (CYP19A1), in drug disposition in the therapeutic setting.

After a single oral dose of 2.5 mg to human subjects, the mean maximum plasma concentration of letrozole was 13 μ M [27]. Owing to the slow elimination half-life, plasma concentrations significantly accumulate with repeated doses, achieving mean

Carbinol metabolite

trough and maximum concentrations of 0.3 and 0.5 μM , respectively, at the steady state [23]. In clinical studies, nonlinear pharmacokinetics have been observed for letrozole at high single doses (up to 30 mg) or after repeated doses (up to 10 mg per day) [23], resulting in an ~ 10 -fold higher plasma exposure than the therapeutic plasma levels in subjects given clinical doses. Large intersubject variation in plasma concentration has generally been observed, regardless of the dose range or regimen used.

Letrozole is cleared from the body by oxidative metabolism to a pharmacologically inactive carbinol metabolite (Fig. 20.2). More than 85% of administered letrozole has been recovered as the glucuronide of the carbinol metabolite [27,28]. Two P450 forms, CYP2A6 and CYP3A4, are reported to mainly contribute to the metabolism, based on *in vitro* biotransformation studies [29,30], but the quantitative contributions of each P450 isoform to the overall clearance, or the contributions of other enzymes such as CYP19A1 (the pharmacological target), remain unclear.

The metabolic activities of individual human liver microsomes showed a significant correlation with coumarin 7-hydroxylase activities (CYP2A6 marker) at a letrozole concentration of $0.5 \mu\text{M}$, and a good correlation was also seen with testosterone 6 β -hydroxylase activities (CYP3A4 marker) at a substrate concentration of $5 \mu\text{M}$. Significantly low carbinol-forming activities were observed in human liver microsomes from individuals possessing *CYP2A6*4/*4* (whole *CYP2A6* gene deletion) at a letrozole concentration of $0.5 \mu\text{M}$. The $V_{\text{max}}/K_{\text{M}}$ value measured for CYP2A6.7 (amino acid substitution type) in human liver microsomes in the presence of anti-CYP3A4 antibodies was approximately sevenfold smaller than that for CYP2A6.1 (wild type). CYP2A6 and CYP3A4 are recognized as catalyzing the conversion of letrozole to its carbinol metabolite *in vitro*, at low and high concentrations of letrozole, respectively [30]. In addition, CYP2A6 has been recently identified as a polymorphic P450 resulting in poor metabolizers associated with the whole gene deletion (*CYP2A6*4*) and/or activity-depressed genes (*CYP2A6*7* and *CYP2A6*9*), which are known to be more abundant in the Asian population [31] than in Caucasian or African populations [32]. Polymorphic variation of CYP2A6 is considered to be relevant to intersubject variation in the therapeutic exposure of letrozole.

20.4 TAMOXIFEN AND CYP2D6

Tamoxifen (Fig. 20.3) is an estrogen receptor (ER) modulator used worldwide in the prevention and treatment of ER-positive breast cancers. The clinical benefit of this agent for the treatment of ER-positive early breast cancer is evident by the eminent

Figure 20.3 Tamoxifen and its metabolites.

reduction in recurrence and mortality rates [33,34]. Despite this success, the mechanisms underlying the ineffectiveness of tamoxifen in a subset of patients are not fully understood; interindividual differences in the formation of active metabolites could be an important factor affecting variability in the response to tamoxifen.

Tamoxifen is a prodrug that requires metabolic activation, carried out mainly by CYP2D6, to elicit its pharmacological activity with clinical outcome [7]. The metabolites 4-hydroxytamoxifen and 4-hydroxy-*N*-desmethyltamoxifen (endoxifen) are believed to be the active therapeutic moieties (Fig. 20.3). Compared with the parent drug, these two metabolites have 100-fold greater affinity to ER and 30- to 100-fold greater potency in suppressing estrogen-dependent cell proliferation [35–37].

The *CYP2D6* gene locus is extremely polymorphic, having over 75 allelic variants (<http://www.cypalleles.ki.se/cyp2d6.htm>), and this contributes to the wide interindividual and ethnic differences in CYP2D6 activity *in vivo*. Women with a poor metabolizer phenotype with respect to CYP2D6, and consequently with low production of the active metabolite, have a greater risk of breast cancer relapse while on tamoxifen, both as a result of genetic variation (e.g., *CYP2D6**4) and also as a result of enzyme inhibition (e.g., by intake of CYP2D6 inhibitor drugs). In Asians, the major defective allele, *CYP2D6**10, causes decreased CYP2D6 activity, and a significantly reduced disease-free survival has been shown for *CYP2D6**10 homozygous patients treated with tamoxifen [38–40] in addition to the minor frequency of the whole gene deletion (*CYP2D6**5). In contrast, an opposite relationship between outcome of tamoxifen treatment and CYP2D6 polymorphism has been published [41]. The basis for this difference is not yet evident. Endocrine therapy tailored to CYP2D6 genotype could be considered for women diagnosed with breast cancer.

Tamoxifen metabolism is mediated by several P450 enzymes, of which CYP2D6 is the most prominent. However, the *in vitro* participation of CYP2C19 in the conversion of tamoxifen to (Z)-4-hydroxytamoxifen, *N*-desmethyltamoxifen, and (E)-4-hydroxytamoxifen and in the trans to cis isomerization of 4-hydroxytamoxifen is well documented (Fig. 20.3), especially at high concentrations [42,43]. In addition, patients

carrying the *CYP2C19**17 rapid activity allele [44] have been shown to have a more favorable clinical outcome during tamoxifen therapy, as measured by the relapse-free time [45]. It is noteworthy that two groups have investigated the effects of the defective *CYP2C19**2 allele on tamoxifen treatment [45,46] but found no significant difference as compared to the wild-type allele, indicating that the *CYP2C19**17 allele might be linked to another polymorphism influencing the phenotype/outcome of the treatment. It is interesting to note that an increased number of *CYP2C19**17 alleles correlated with a decreased risk of suffering from breast cancer [47]. These findings collectively suggest that more studies are needed before application of *CYP2D6* and *CYP2C19* pharmacogenetics to tamoxifen prescription can become a reality. Large prospective studies in this area are necessary to determine the benefit of *CYP2D6* genotyping in the selection of ER modulators for breast cancer.

20.5 THALIDOMIDE AND CYP3A4/5

Thalidomide [α -(*N*-phthalimido)glutarimide] (Fig. 20.4) was withdrawn from clinical use in the early 1960s because of its teratogenic effects in humans but has been approved for the treatment of refractory multiple myeloma by the United States and Japan since 2000 [48,49]. The *CYP2C19* genotype is reported to be associated with cancer treatment outcome using thalidomide [50], and the clinical response rate in 62 patients undergoing thalidomide (with dexamethasone) treatment was twice as high in extensive metabolizers than in poor metabolizers [50]. Decreased formation of active thalidomide metabolites (if those contribute to therapy) would be expected with defective *CYP2C19* alleles compared to the wild type [50]. No evidence has been obtained for drug interactions between thalidomide and hormonal contraceptives [51,52].

Thalidomide-inhibited *CYP2C19*-dependent (*S*)-mephenytoin 4'-hydroxylation at high concentrations but enhanced *CYP3A5*-dependent midazolam hydroxylation and

Figure 20.4 Thalidomide and its metabolites.

cyclosporine A clearance at clinically relevant concentrations [53]. Two hydroxylated metabolites of thalidomide (5-hydroxythalidomide and 5'-hydroxythalidomide) are reportedly formed at very low concentrations after incubation with recombinant human CYP2C19 [54]. Recently, although ligand cooperativity with CYP3A5 similar to that for CYP3A4 has been observed [55] and homotropic cooperativity of CYP3A5 with thalidomide was shown [56]. Liquid chromatography–mass spectrometry analysis revealed formation of a glutathione conjugate from (*R*)- and (*S*)-5-hydroxythalidomide, a process catalyzed by liver microsomal CYP3A4 and CYP3A5 in the presence of glutathione (assigned as a conjugate of 5-hydroxythalidomide formed on the phenyl ring) (Fig. 20.4) [56]. These findings established that human CYP3A4 and CYP3A5 mediate thalidomide 5-hydroxylation and further oxidation leads to a glutathione conjugate, which may be of relevance in the pharmacological and toxicological actions of thalidomide.

20.6 IRINOTECAN AND UDP-GLUCURONOSYLTRANSFERASE 1A1

Irinotecan is mainly used in the treatment of colon cancer, particularly in combination with other chemotherapy agents. Irinotecan (known as *CPT-11* during development), a semi-synthetic analogue of the natural alkaloid camptothecin, is activated by enzymatic hydrolysis to SN-38 (Fig. 20.5), an inhibitor of topoisomerase I. The inhibition of topoisomerase I by the active metabolite SN-38 leads to inhibition of both DNA replication and transcription. SN-38 is inactivated by glucuronidation by uridine diphosphate glucuronosyltransferase 1A1 (UGT1A1).

Subjects harboring the *UGT1A1**28 gene (called *TA₇* in the promoter region) express fewer UGT1A1 enzymes in their livers and often suffer from Gilbert's syndrome [57]. During chemotherapy, these patients effectively receive a larger than expected dose because their bodies are unable to clear irinotecan as fast as other subjects; this corresponds to higher incidences of severe diarrhea and neutropenia [58]. A clinical study was performed in 2004 that validated prospectively both the association of *UGT1A1**28 with greater toxicity in patients undergoing treatment with irinotecan and the ability of genetic testing to predict toxicity before chemotherapy administration [59]. The US FDA made changes to the labeling of irinotecan to add pharmacogenomics recommendations regarding which patients carrying genetic polymorphism of the *UGT1A1* gene

Figure 20.5 Irinotecan and its metabolite.

(specifically *UGT1A1**28) might benefit from reduced drug doses. Irinotecan is one of the first widely used chemotherapy agents for which personalized medicine according to genotype has been applied [60].

20.7 6-MERCAPTOPURINE AND THIOPURINE-S-METHYLTRANSFERASE

6-Mercaptopurine (Fig. 20.6) is used to treat leukemia and pediatric non-Hodgkin's lymphoma and is an immunosuppressive agent [61]. 6-Mercaptopurine inhibits purine nucleotide synthesis and metabolism and alters the synthesis and function of RNA and DNA. Some of the adverse reactions of taking 6-mercaptopurine include black or tarry stools (melena), bloody stools, and bloody urine [62].

6-Mercaptopurine causes myelosuppression, suppressing the production of white and red blood cells and may be toxic to bone marrow. Weekly blood counts are recommended for patients on 6-mercaptopurine, and treatment is interrupted if there is an unexplained abnormally large drop in white blood cell or any other blood count. Subjects who exhibit myelosuppression or bone marrow toxicity should be tested for thiopurine-S-methyltransferase (TPMT) enzyme deficiency [63,64]. Although patients with TPMT deficiency are much more likely to develop dangerous myelosuppression [65], it may be possible to continue using 6-mercaptopurine at a lower dose [66].

20.8 CARBOPLATIN AND HYPERBARIC OXYGENATION

Carboplatin (Fig. 20.7), *cis*-diammine-1,1-cyclobutane dicarboxylate platinum(II), is a second-generation platinum antineoplastic agent with modest activity against brain tumors [67]. The efficacy of intravenous administration of 400-mg carboplatin/m²

Figure 20.6 Chemical structure of 6-mercaptopurine.

Figure 20.7 Chemical structure of carboplatin.

body surface area over 60 min combined with hyperbaric oxygenation (HBO) therapy (0.2 MPa for 60 min) was investigated in several patients with malignant or brainstem gliomas [68]. Plasma ultrafiltrate samples were analyzed by high performance liquid chromatography [69] to evaluate the relationship between efficacy and pharmacokinetics. Brain tumor response was evaluated by magnetic resonance imaging as a function of maximum plasma concentration, area under the curve, or mean residence time (MRT) for carboplatin. The MRT for carboplatin in the complete or partial response group was significantly longer than that in the progressive disease group [68], but maximum plasma concentration and area under the curve had no effect on outcome. These results suggest that HBO therapy prolongs the biological residence time of carboplatin with modification of chemotherapy and/or clinical antitumor effects in patients with malignant gliomas.

Carboplatin had low brain penetration potential in a cultured blood–brain barrier system. Therefore, HBO therapy at 0.2 MPa for 60 min resulted in apparently higher concentrations of carboplatin in the brain than expected. The present findings of good clinical response may suggest that HBO therapy modifies the pharmacokinetics of carboplatin. With a rat model, changes in the pharmacokinetics of carboplatin with HBO therapy were also suggested by the detection of carboplatin in the brain at 60 min (from the start of administration) after HBO treatment at 0.2 MPa for 20 min [70,71]. Oxygen-induced cerebral vasoconstriction could result in some modification of drug pharmacokinetics, presumably because of various biochemical changes in the brain such as inactivation of intracellular enzyme systems or changes in blood flow rates. Any resultant prolonged biological half-life of carboplatin might explain the effect of combined cisplatin/HBO therapy for malignant gliomas.

Carboplatin had similar endothelial permeability to that of doxorubicin or verapamil, typical P-glycoprotein substrates, in an *in vitro* blood–brain barrier system [71]. Increased permeability of P-glycoprotein-dependent carboplatin as a result of HBO (similar to that resulting from verapamil) may rapidly reach pharmacologically significant concentrations in the central nervous system. Moreover, increased distribution of carboplatin to rat brains with the aid of HBO *in vivo* has been reported [70]. Prolonged biological residence time of carboplatin may be achieved by combination with HBO therapy, resulting in improved efficacy against malignant gliomas. The MRT may be important for predicting continuation or modification of chemotherapy and/or clinical antitumor effects on malignant gliomas.

20.9 CONCLUSIONS

P450 enzymes responsible for the activation or inactivation of anticancer drugs are polymorphic, and much research has been directed at elucidating the ways in which genetic polymorphism in the corresponding genes can affect the efficacy of cancer therapy. With respect to anticancer therapy, the influence of CYP2D6 polymorphism on tamoxifen treatment merits additional study to establish the relationship. Further interesting results can be anticipated leading to more detailed labeling of irinotecan with pharmacogenomic recommendations on which patients carrying genetic polymorphism of the *UGT1A1* gene (specifically *UGT1A1**28) should perhaps receive reduced drug doses. In the future, increased understanding regarding the role of P450 expression will also provide additional information on the ADME of anticancer drugs.

21.1 SUMMARY OF CARDIOVASCULAR DRUG METABOLISM

Effective drug therapy for cardiovascular diseases (CVDs) is determined by systemic exposure of the therapeutic agent and specificity for the target. Drug concentration at the target site is dependent on the distributional characteristics of the drug (e.g., membrane permeability and unbound fraction) and by its concentration in blood or plasma. Since the systemic exposure of a drug is usually directly related to maximize desired effect and minimize undesired effects, the factors that influence the concentration of the agent over time determine the success of the therapy. Accordingly, those factors that control clearance and elimination of the drug ultimately control safety and effectiveness.

Clearance of most cardiovascular drugs is mediated by one or more enzymatic or transport processes. Isoforms of cytochrome P450 (CYP) make up the most prevalent oxidative or the so-called phase I clearance pathway. Some cardiovascular (CV) drugs are metabolized by primary or secondary conjugation, forming glucuronides, sulfates,

or other conjugates, the so-called phase II pathway. A few drugs, notably angiotensin-converting enzyme (ACE) inhibitors are metabolized by hydrolysis pathways. Although the human CYP superfamily is composed of more than 50 members, CV drugs interact primarily with CYP3A4, 2D6, or 2C9. Given that CYP3A4 is the most highly expressed CYP in the liver and has the largest active site, the association with CV drug metabolism is not surprising. However, liver CYP2D6 abundance is relatively low (about 2% of total) and the active site more restricted, yet it is the primary clearance mechanism for a number of CV drugs.

The most notable CV adverse events have stemmed from drug interactions due to changes in the enzymatic clearance process. Enzymatic processes are subject to saturation, inhibition, induction, and genetic polymorphism, each of which can change systemic exposure and therapeutic efficacy. In the case of the thienopyridine platelet inhibitors, CYP2C19 directly controls effectiveness by virtue of the activation pathway for generation of the active thiols. Other oxidative or hydrolytic enzymes also control drug clearance, particularly in the case of ACE inhibitors.

The enzymatic and transporter processes that control drug clearance can be capacity-limited processes, subject to variation in activity or expression due to competing substrates or regulation by intrinsic and external factors. Each of these attributes has the potential to influence effectiveness of cardiovascular drugs as well as cardiotoxic effects of noncardiovascular therapeutics.

21.2 DRUG-METABOLIZING ENZYMES

Drug-metabolizing enzymes (DMEs) play an important role in cardiovascular health and disease. These enzymes, especially CYP, control the clearance of many small-molecule cardiovascular drugs and are involved in the metabolism of endogenous substances (such as leukotrienes, steroids, and bile acid) that are in turn implicated in several cardiovascular-related pathways, including inflammation, lipid metabolism, and blood pressure regulation. In general, drugs can be metabolized by oxidation, reduction, hydrolysis, or conjugation, generally accepted pathways for excretion of drugs from the body. The enzymes involved in metabolism are present in many tissues but are most concentrated in the liver. These enzymes are divided into two groups. Phase I metabolizing enzymes, including CYP450s and flavin monooxygenases (FMOs), catalyze the introduction of an oxygen atom into substrate molecules often resulting in hydroxylation, dealkylation, and hydrolysis. Phase II reactions involve conjugation with an endogenous or exogenous substance. Phase II conjugating enzymes include the UDP-glucuronosyltransferases (UGTs), sulfotransferases (SULTs), *N*-acetyltransferases (NATs), and glutathione transferases (GSTs). Metabolites formed from either or both processes are more polar and more readily excreted by renal and/or hepatobiliary processes. Among these enzymes, CYPs often play a critical role in the disposition of cardiovascular drugs.

21.3 CYTOCHROME P450

CYP is a superfamily of hemoprotein found in human liver and other tissues such as small intestine that play an important role in the metabolism of exogenous as well

TABLE 21.1 Cardiovascular Drugs as CYP Substrates

Substrates	CYP3A4/5	CYP2C19	CYP2C8	CYP2C9	CYP2D6	CYP1A2
<i>Lipid lowering agents</i>

as endogenous molecules. CYP enzymes are so named because they absorb light at a wavelength of 450 nm when carbon monoxide binds to the enzymes at their reduced state. There are more than 50 CYP enzymes in human, although many of these enzymes have the capacity to metabolize drugs, the majority of CYP-mediated drug metabolism in human is catalyzed by subfamily CYP3A, 2C, 2D6, and 1A enzymes (Table 21.1).

21.3.1 Cytochrome P450 3A Subfamily

CYP3A is the most highly expressed isoform in human, representing ~30% of the spectroscopically detectable CYP in the liver [1] and have an important role in the oxidative, peroxidative, and reductive metabolism of endogenous steroids, many procarcinogens, and at least 50% of all drugs. The most abundant CYP3A isoform expressed in liver and gut is CYP3A4 [2]. Interindividual expression of CYP3A4 can vary by 50-fold among individuals and functionality (i.e., drug clearance) by about 20-fold. High interindividual variation can be associated with genetic and environmental factors [3].

Despite extensive efforts to identify genetic variation within the CYP3A4 gene associated with altered enzyme activity, multiple groups have failed to identify common CYP3A4 genotypes that can explain variable CYP3A4 expression [4,5]. Although the substrate specificity of CYP3A5 is similar to CYP3A4, it is thought to be less important for drug metabolism because it is expressed at only 10–30% of CYP3A4 levels. A unique characteristic of CYP3A is the autoactivation or heteroactivation, which is associated with the increased catalytic activity of a particular substrate by the addition of another xenobiotic or same substrate. This positive cooperativity or activation of CYP3A occurs with midazolam by α -naphthoflavone, alprazolam, flunitrazepam, and triazolam by testosterone and so on [6]. The clinical significance of activation is not clear, complicating the interpretation of *in vitro* studies and extrapolation to human pharmacokinetics (PK).

CYP3A4 is often implicated in drug–drug interactions (DDIs) as a result of inhibition or induction by drugs or dietary components, sometimes leading to adverse drug reactions. Azole antifungal agents, ketoconazole, itraconazole, and fluconazole are potent competitive CYP3A4 inhibitors with K_i values below $1\ \mu\text{M}$. Macrolides such as erythromycin, and troleandomycin and antidepressant such as fluoxetine and nortriptyline are CYP3A inhibitors acting via the formation of metabolite–intermediate complexes. HIV protease inhibitors such as ritonavir and 17- α -ethinyl-substituted steroids have been found to be mechanism-based CYP3A4 inhibitors. Rifampin, carbamazepine, phenytoin, and phenobarbital are reported as potent CYP3A inducers. Terfenadine, a well-known early example of drug interactions, was approved in the United States in 1985 for the treatment of seasonal allergic rhinitis. The drug is primarily eliminated by CYP3A4-mediated metabolism. Coadministration with potent CYP3A4 inhibitors such as ketoconazole and erythromycin markedly elevated terfenadine plasma level to produce serious cardiac arrhythmias leading to death in some instances [7]. Terfenadine was removed from the market when fexofenadine, the active metabolite of terfenadine, was approved and marketed. Fexofenadine does not block cardiac potassium channels. Prolonged QT interval and syncope were also reported for nonsedating antihistamine, astemizole, when coadministered with ketoconazole, itraconazole, or erythromycin [8]. Nevertheless, most clinically significant drug interactions result agents with a narrow therapeutic index coadministered potent inhibitors or inducers. More modest interactions are generally of lesser concern since the consequences are within the window of normal variability.

21.3.2 Cytochrome P450 2D6 Subfamily

CYP2D6 accounts for about 2% of total hepatic CYP but is responsible for about 25% of the metabolism of known drugs, including many of those used in the treatment of CVD. Genetic variants of CYP2D6, which result in varying levels of metabolic activity, are of clinical importance in some settings. Currently, more than 75 allelic variants have been identified; all variant alleles are presented at the home page of the human CYP allele nomenclature committee (<http://www.imm.ki.se/cypalleles/cyp2d6.htm>). The variant CYP2D6 alleles result from point mutations, deletion, or duplication of the entire gene and result in an abolished, decreased, normal, increased, or qualitatively altered catalytic activity. Establishing which phenotype an individual has often depends on the administration of a probe drug that is a substrate of CYP2D6 (e.g., dextromethorphan, debrisoquine, or sparteine) and measuring the metabolite–parent

ratio. However, there are some limitations for estimating *in vivo* enzyme activity using urinary metabolite to parent ratio [9]. For dextromethorphan, there is not a linear correlation between enzyme activity and urinary parent/metabolite ratio, probably a result of pH dependence and renal or hepatic transport. Dextromethorphan is also a substrate of CYP3A. In addition, cost and time effectiveness of urine analysis have precluded widespread, routine phenotyping determinations. As a practical alternative, genotyping of the CYP2D6 gene is increasingly used in clinical practice to assess the risk of undesired drug effects or therapeutic failure for individual patient and eventually to apply a dose adjustment or change in therapeutic strategy. Considering the growing number of CYP2D6 alleles and corresponding ranges of activity, prediction of a subject's phenotype based on their genotype is a significant challenge. Currently, standard process of translating genotype data into a phenotype prediction is not established. Several different genotype–phenotype systems for CYP2D6 have been proposed, including the CYP2D6 “activity score” (AS) system [9,10]. In this system, over 25 CYP2D6 allelic variants were genotyped in 672 subjects of Caucasian and African-American heritage. For each variant CYP2D6 allele, a value relative to the fully functional CYP2D6*1 reference allele is assigned based on published literature on *in vivo* and *in vitro* activity toward commonly used probe drug, such as dextromethorphan (DM), debrisoquine, or sparteine. The AS of a genotype is the sum of values assigned to each allele with the assumption of both alleles contributing equally to overall CYP2D6 activity. A total 95 genotypes are categorized into six AS groups. A final model (AS-model A) is generated to relate AS groups to CYP2D6 activity based on urinary metabolite data (DM/dextromethorphan ratios). The authors also emphasize that the probability of belonging to a particular phenotype group using AS-model A may be more accurately predicted if ethnicity is considered. Although there are some limitations of using dextromethorphan urinary ratios to estimate *in vivo* enzyme activity, AS system is a simplified tool for translating vast genotype data into CYP2D6 activity prediction.

It is important to establish a more quantitative system to precisely predict CYP2D6 activity *in vivo* and transform this information to dose adjustment for individual patient for drugs that are primarily metabolized by CYP2D6, such as the antiarrhythmics flecainide and propafenone or β -blocker metoprolol.

21.3.3 The Cytochrome P450 2C Subfamily

The CYP2C subfamily of P450 enzymes metabolize ~20% of clinically used drugs; CYP2C8, 2C9, and 2C19 are of clinical importance. Next to CYP3A4, CYP2C9 is the most predominantly expressed CYP enzyme in the human liver and the most highly expressed of the 2C subfamily. It metabolizes many clinically important drugs, including the diabetic agent tolbutamide, the anticonvulsant phenytoin, the *S*-enantiomer of the anticoagulant warfarin, Δ^1 -tetrahydrocannabinol, and numerous anti-inflammatory drugs such as ibuprofen, diclofenac, piroxicam, tenoxicam, and mefenamic acid [11], the antihypertensive losartan [12], the antidiabetic drug glipizide, and the diuretic torsemide [13]. Defective alleles of CYP2C9 [14,15] have the potential to affect the safety of those CYP2C9 drugs with smaller therapeutic indices such as warfarin, phenytoin, and certain antidiabetic drugs. CYP2C9*2 and 2C9*3 are known to affect catalytic function. CYP2C9*2 has a frequency of ~8–10% in Caucasians but has a lower frequency in African-Americans and appears to be virtually absent in Asians

[16,17]. CYP2C9*3 has a frequency of ~6% in Caucasians (the frequency of homozygous CYP2C9*3 is 0.3%); the frequency in Asians is probably 2%. Results from the human studies published to date have concluded that CYP2C9 genotype contributes significantly to the variability in disposition and dose–response of substrates such as warfarin, phenytoin, tolbutamide, glipizide, losartan, candesartan, irbesartan, ibuprofen, flurbiprofen, and celecoxib. Individuals carrying the CYP2C9*2 and *3 alleles also have lower warfarin and phenytoin daily dose requirements and appear more susceptible to adverse events during the initiation of therapy. CYP2C9 genotype-guided dosing may be clinically useful and warrants prospective investigation [18].

CYP2C19 is the principle catalyst for metabolism of several well-known drugs such as omeprazole, diazepam, and mephenytoin; it is also responsible for activation of proguanil to cycloguanil. Genetic variation attributable to CYP2C19 was first described in the 1980s [19], about the same time, the thienopyridine antiplatelet drug ticlopidine was brought to market. Although clopidogrel is the current standard of care for coronary artery disease patients undergoing a percutaneous coronary intervention (PCI), ~25% of the patients experience a subtherapeutic antiplatelet response [20]. Clopidogrel is a prodrug, about 85% of the clopidogrel dose is hydrolyzed by esterase to an inactive metabolite, and the remaining clopidogrel is available for the conversion to the active metabolite via two sequential metabolism-mediated steps [21]. The role of CYP2C19 in its metabolism was unknown until several years after its approval that a report suggested possible polymorphism in CYP2C19 might be a cause of variable pharmacodynamic response [22]. This was confirmed in a number of subsequent reports, thoroughly reviewed by Farid *et al.*, pointing to the conclusion that CYP2C19 is the major contributor to 2-oxo-clopidogrel (active metabolite) formation from clopidogrel. CYP2C19 variant allele carriers exhibit a significantly lower capacity to metabolize clopidogrel and inhibit platelet activation and are therefore at higher risk of adverse cardiovascular events. Finally resulting in a US Food and Drug Administration (FDA) recommendation that patients be genotyped for CYP2C19 PM to avoid inadequate platelet inhibition [20].

21.3.4 Cytochrome P450 1A2 Subfamily

CYP1A2 accounts for ~13% of total hepatic CYP expression [1], CYP1A2 shows up to 40-fold variability between individuals and corresponding variability of enzyme activity and drug metabolism. Although there is evidence that genetic factors have major influence on observed enzyme activity [23], the role of polymorphisms identified to date is unclear. Apart from smoking, coadministration of drugs that are inhibitors, inducers, or competing substrates for CYP1A2 can influence CYP1A2 activity [24]. Phenotyping represent a suitable method to shed light on the actual enzyme activity. Caffeine is the most commonly used substance for CYP1A2 phenotyping. The first step in its metabolism is almost exclusively mediated by CYP1A2, and concentrations in biological matrices can be determined using a simple HPLC method. An epidemiological study examining the role of diet and caffeine in cardiovascular health found an association of CYP1A1*1F allele with nonfatal myocardial infarction (MI) [25]. Carriers of *1F allele are “slow metabolizers” of caffeine compared to wild type, probably due to reduced expression of the enzyme. Overall, the involvement of CYP1A2 in cardiovascular drug metabolism is relatively low.

21.3.5 Other Cytochrome P450s and Phase II Enzymes

Other CYP enzymes such as CYP2B6, CYP1A1, UGT, or SULT are generally not critically involved in the metabolism of CV drugs, although it should be noted that 1-*O*-glucuronide of gemfibrozil was found to be a potent mechanism-based CYP2C8 inhibitor. Several reported drug interactions between gemfibrozil and CYP2C8 substrates such as antidiabetic agents rosiglitazone and pioglitazone are probably due to CYP2C8 inhibition by 1-*O*-glucuronide of gemfibrozil [26,27].

21.4 DRUG-METABOLIZING ENZYMES EXPRESSED IN THE CARDIOVASCULAR SYSTEM

Although significant efforts have been focused on hepatic CYP-mediated cardiovascular drug interactions and genetic polymorphism of hepatic CYPs leading to adverse drug events, limited information is available regarding cardiac metabolism [28,29]. Differences in cardiac drug metabolism may also influence pharmacological efficacy or adverse drug effects. For example, lack of efficacy for ACE inhibitors in treating right-ventricular hypertrophy was attributed to metabolic inactivation of drug in the right ventricle but not in the left ventricle [30]. Further, endogenous CYP metabolites, epoxyeicosatrienoic acids (EETs) and hydroxyeicosatetraenoic acid (HETEs), prostacyclin (PGI₂), aldosterone, and sex hormones have pivotal roles in the maintenance of cardiovascular health.

Evidence for expression or at least transcription has been observed for a number of CYPs in cardiac tissue. CYPs identified in mammalian species include CYP1A1, 1B1, 2A1/2, 2A6/7, 2B6/7, 2C8/9, 2D6, 2E1, 2J2, 3A4, 4A1/2, 4B1, and 4F1 [29].

CYP1A1 mRNA was detected in the right ventricle, pulmonary aorta, ascending aorta, and the left atrium of patients with dilated cardiomyopathy and in the left ventricle of healthy subjects [31]. CYP1A2 mRNA is absent in healthy human heart [32]. CYP1B1 mRNA expression was observed in the normal human heart in relatively high abundance [32]. CYP1A1 mRNA and CYP1B1 are inducible in vascular smooth muscle cells (SMCs) [33].

In humans, CYP2B, 2C, 2D6, 2E1, and 2J2 were detected in heart tissues [30,34]. CYP2B6/7, 2C8-19, and 2D6 were predominantly expressed in the right ventricle; the unilateral expression of the 2D6 gene in right-ventricular tissue [30], whereas CYP2E1 mRNA was expressed in various parts of the heart, including the right and left atria, right and left ventricle, aorta, and the ventricular septum. CYP2E1 protein was found in the endocardium and coronary vessels of human autopsy samples [35]. CYP2C8, 2C9, and 2J2 mRNA and protein are present in various amounts in the human heart, coronary artery, and aorta tissues [34]. CYP2J2 mRNA levels in the heart were ~10 times higher than those of CYP2C9 or 2C8. CYP2J2 and 2C8 protein were shown to be predominant CYP expressed in human heart, CYP2J2 is also expressed in blood vessels. Beside higher expression in heart tissue, CYP2J2 is most abundant in small intestine [36,37]. In fact, CYP2J2 was shown to be responsible for the first-pass metabolism of ebastine and astemizole [38]. In a recent screening of CYP2J2 substrates using 139 marketed therapeutic agents, several novel substrates including terfenadine, astemizole, amiodarone, albendazole, danazol, thioridazine, tamoxifen, cyclosporine, nabumetone, and mesoridazine were identified [39]. Interestingly, the substrates identified for CYP2J2

are also metabolized by CYP3A4. Although CYP2J2 active site can accommodate large molecules such as CYP3A4, CYP2J2 metabolism was more restricted to a single site of molecule, whereas CYP3A4 commonly metabolizes compounds at multiple sites of molecules. Little information is available on the expression of CYP3A family in cardiovascular tissues. CYP3A4/5/7 mRNA was not found in human heart tissues [30]. CYP4F3/12 mRNA was detected in the human and dog heart [40,41]. The role and regulation of CYP expression in the heart is not clear but it is unlikely that it plays any meaningful role in drug clearance.

21.5 ROLE OF CYP METABOLITES IN CARDIOVASCULAR HEALTH

Metabolism of eicosanoids in the cardiovascular system is well described and partly dependent on CYPs. There are three major metabolic pathways involved in arachidonic acid metabolism [42]. First, hydroperoxyeicosatetraenoic acids (HPETEs) and dihydroxyeicosatetraenoic acid (DiHETE) are formed by lipoxygenase and subsequently converted to HETEs by peroxidases; in the second pathway, cyclooxygenase catalyzes arachidonic acid to prostaglandin G₂, in a subsequent peroxidase reaction, PGG₂ undergoes a two-electron reduction to PGH₂. PGH₂ can be further metabolized to other eicosanoids such as PGI₂ and thromboxane A₂ (TXA₂). Third, CYP metabolizes arachidonic acid to regio- and stereospecific EET and HETEs.

Several CYPs can metabolize arachidonic acid to EETs, including CYP1A, 2B, 2C, 2E, and 2J subfamilies [43,44]. CYP2J isoforms have been proposed as the predominant enzymes responsible for epoxidation of endogenous arachidonic acid pools in human and rat heart [36,45]. The induction of CYP2C in native porcine coronary artery endothelial cells by β -naphthoflavone enhances the formation of EET, as well as endothelium-derived hyperpolarizing factor (EDHF)-mediated hyperpolarization and relaxation. Transfection of coronary arteries with CYP2C antisense oligonucleotides results in decreased levels of CYP2C and attenuates EDHF-mediated vascular responses, indicating that the EDHF synthase in the porcine coronary vascular bed is a CYP2C isoform. EETs are important components of many intracellular signaling pathways involved in vasodilatory, anti-inflammatory, and cardioprotective responses in cardiovascular system [29].

In addition to generation of the vasorelaxant 11,12-EET, CYP2C9 was shown to be potential major source of reactive oxygen species (ROS) [46]. ROS generated in arteries reacts with NO to produce peroxynitrite (ONOO⁻) resulting in a reduction of NO bioavailability that impairs endothelium-dependent vascular function in atherosclerosis [47]. Hunter *et al.* recently demonstrated that CYP2C inhibition during the peritransplant period prevented development of cardiac allograft vasculopathy (CAV) by inhibiting early SMC proliferation and intimal hyperplasia. This effect could also be a result of reduced postischemic oxidative damage, contributing to increased NO bioavailability and/or prevention of interferon γ (IFN- γ) production [48]. Interestingly, it was reported that concomitant pretreatment with 11,12- or 14,15-EET in combination with the free radical scavenger, 2-mercaptopropionyl glycine (2-MPG), completely abolished the cardioprotective effect of 11,12- and 14,15-EETs, suggesting part of the cardioprotective effects of EETs in rat hearts against infarction is the result of an initial burst of ROS and subsequent activation of both the sarcK_{ATP} and mitoK_{ATP} channel [49].

CYP ω -hydroxylases, such as CYP4A and 4F, biosynthesize 20-HETEs [50]. CYP1A1/2, 1B1, and 2E1 were reported to produce different regioisomers of HETE [28]. HET0016 is a potent and fairly selective inhibitor of 20-HETE formation with little effect on the activities of cyclooxygenase and other CYP enzymes [51]. The IC_{50} values of HET0016 for the formation of 20-HETE by human recombinant CYP4F2, 4F3, and 4A11 enzymes are 125, 100, and 42 nM, respectively [52]. In addition to CYP inhibitors, antisense of cDNA oligonucleotides (ODNs) has been developed to block the formation of 20-HETE. CYP4A1/4A2/4A3-specific antisense ODNs can inhibit protein expression and the corresponding catalytic activity [53]. The role of HETEs in the control of cardiovascular functions has been reviewed [54]. Altered expression and function of arachidonic acid ω -hydroxylases in models of hypertension, diabetes, inflammation, and pregnancy suggest that 20-HETE may be involved in the pathogenesis of these diseases [50].

21.6 DRUG-DRUG INTERACTIONS

Pharmacokinetic drug interactions can cause excess or insufficient drug exposure leading to, respectively, toxicity or ineffectiveness and in some cases to termination of drug development, severe prescribing restriction, and withdrawal of drugs from the market. The majority of DDIs stem from changes in enzymatic capacity. The existing guidance issued by the FDA covers mainly CYP450-mediated drug interactions, the importance of other mechanisms, such as transporter-based drug interaction, non-CYP-based interaction, and interactions involving therapeutic proteins, have been recognized more recently. Many cardiovascular drugs are metabolized in the liver; CYP3A4, 2D6, and 2C9 are primary enzymes mediating cardiovascular drug interactions. CYP inducers such as phenytoin, barbiturates, rifampin, and St John's wort can induce CYP3A4, 2B6, and 2C8/9 and increase metabolism of susceptible cardiovascular drugs (e.g., some statins, nifedipine, or warfarin), resulting in decreased plasma concentrations and reduced efficacy. On the other hand, systemic exposure of cardiovascular drugs can be increased by potent CYP inhibitors (e.g., erythromycin, grapefruit juice, or omeprazole).

Some cardiovascular drugs are transporter substrates or inhibitors. For example, most statins are hepatic organic anion transporting polypeptide (OATP)1B1/1B3 substrates; cyclosporine causes up to 20-fold increase in area-under-the-curve (AUC) values of statins in organ transplant patient via OATP1B1/1B3 inhibition leading to greater risk of myopathy [55]. Quinidine and verapamil can cause significant increase in digoxin absorption via gut P-glycoprotein (PGP) inhibition [56].

The interaction between clopidogrel, an antiplatelet drug, and omeprazole, a proton pump inhibitor, is illustrated in words from a regulatory agency. "New data show that when clopidogrel and omeprazole are taken together, the effectiveness of clopidogrel is reduced. Patients at risk for heart attacks or strokes who use clopidogrel to prevent blood clots will not get the full effect of this medicine if they are also taking omeprazole." The updated label acknowledges that "concomitant use of drugs that inhibit CYP2C19 (e.g., omeprazole) should be discouraged." The underlying mechanism for this drug interaction is that omeprazole inhibits the CYP2C19, which is the key enzyme for the conversion of clopidogrel into its active form [57]. Other examples of adverse pharmacokinetic drug interaction include increased risk of myopathy with

statins during the coadministration of gemfibrozil via CYP2C8 inhibition [58] and market withdrawals of mibefradil, a calcium channel blocker, because of severe interactions with multiple drugs via inhibition of CYP3A4 and PGP [59]. Detailed drug interactions of major classes of cardiovascular drugs are discussed in later sections.

Of course, noncardiovascular drug interactions may produce significant cardiovascular side effects. Coadministration of CYP3A4 inhibitors (such as ketoconazole, itraconazole, and erythromycin) with terfenadine, methadone, or cisapride have been reported to increase plasma concentration of these drugs and the risk of Torsade de Pointes [56].

21.7 TRANSPORTERS IN CV DRUG METABOLISM

Although more than 400 membrane transporters have been identified in humans, 7 transporters account for much of the apparent drug transport activity in humans: two efflux transporters [PGP and breast cancer resistance protein (BCRP)] and five uptake transporters (OCT2, OAT1, OAT3, OATP1B1, and OATP1B3) [60]. The efflux transporters PGP and BCRP are both members of the ATP-binding cassette (ABC) family and function on the apical or luminal side of the intestinal epithelia, kidney proximal tubules, hepatocytes (canalicular membrane), and blood–brain barrier (capillary endothelial cells). The five uptake transporters are members of the solute carrier (SLC) family. OATP1B1 and OATP1B3 function on the sinusoidal side (blood side) of hepatocytes. OCT2, OAT1, and OAT3 function as uptake transporters on the basolateral side (blood side) of kidney proximal tubule cells and function by selectively pumping substrates from the blood. In this way, transporters serve a protective role by pumping substrates out of the cells. Examination of recent publications on drug transporters shows considerable involvement of cardiovascular drugs [60]. Indeed, the field of membrane transporters has grown in part because of the need to understand the role of uptake and efflux transporters in the disposition of the statin drugs. Of the five major drug transporter families, DDIs with four are characterized primarily by cardiovascular drugs [60]. Although the discovery and understanding of transporters in drug disposition and interactions has lagged that of CYPs, progress in recent years has provided a much more complete understanding of the situation to the point where guidelines for evaluation of DDI has been proposed and the role of transporters in disposition of drugs is expected.

The efflux transporter PGP (MDR1 and ABCB1) appears to serve as a protective mechanism by pumping its substrate back into the lumen of the small intestine, out of the brain, liver, and kidney. It is a member of the ABC family of transporters, characterized by ATP-dependent directional flow. It has broad substrate specificity and plays an important role in limiting the absorption of many drugs through the gut wall and blood–brain barrier. It also facilitates excretion of many drug substrates from the liver and kidney. The cardiac glycoside digoxin is a prototypic inhibitor of PGP.

BCRP is a related ABC transporter expressed in tissues similar to PGP and functioning in similar manner but with different overlapping substrate specificity. Although it might play a role in the disposition of some statins, it appears to have few interactions with cardiac drugs.

The OATP family represents a family of SLC transporters with substrate specificity for amphiphilic compounds. Notable are OATP1B1 and OATP1B3, both of which

appear to be involved in hepatic uptake of statins and might be important in controlling PK and toxicity of some statins.

Two additional transporters that have limited drug substrates but nevertheless important for disposition of ACE inhibitors (e.g., zofenopril and fosinopril) are PEPT1 and PEPT2. Both are members of the SLC family, functioning as uptake transporters on the apical membrane (i.e., luminal side) of intestinal epithelia and kidney proximal tubule cells.

Although some drugs are cleared solely by metabolism involving one or more enzymes and a few are cleared only by transporters, many are cleared by a combination of transporters and DMEs. This can result in vectorial transport of some drugs or complex disposition interactions for others [61].

Bosentan, a dual antagonist of endothelins A and B, is used in treatment of pulmonary artery hypertension. Although its clearance is dependent on the CYP-mediated metabolism, the hepatic uptake via OATP1B1 and 1B3 becomes rate determining in the overall elimination [62].

21.8 BIOMARKERS AND METABOLOMICS

CVD is one of the major causes of human mortality. Methods to minimize CVD risk is a major challenge in the prevention and treatment of CVD. Clinical assessment is the keystone of patient management; however, such evaluation has its limitations [63]. Biomarkers could provide an important approach to understand the spectrum of CVD with applications in at least five areas: screening, diagnosis, prognostication, prediction of disease recurrence, and therapeutic monitoring of CVD [64]. However, close scrutiny of a range of biomarker studies shows shortcomings of some biomarker hopes [65].

The so-called metabolomics is the study of complex metabolite profiles in biological samples, such as urine, plasma, cerebral spinal fluid, or tissue biopsies. Disease changes the concentration and fluxes of small biochemicals that may be captured by metabolite fingerprint in the cells, tissues, and biofluids. In contrast to classical biochemical approaches that often focus on single metabolites or reactions, metabolomics involves the collections of quantitative data on broad series of metabolites in an attempt to gain an overall understanding of metabolism and/or metabolic dynamics associated with disease status and drug action [66]. The metabolome consists of a variety of chemicals with different physicochemical properties such as amino acids, peptide, glucose, lipids, organic acid, nucleotides, ATP, and biogenic amine neurotransmitters. The large numbers of metabolites present in human (over 20,000) and their wide concentration range spreading over nine orders of magnitude make it impossible to achieve with a single analytical method. The two most important tools employed presently in metabolomics are nuclear magnetic resonance (NMR) spectroscopy and mass spectrometry (MS) [67–69].

Sabatine *et al.* [70] reported the application of metabolomics to acute myocardial ischemia. Metabolite profiles in plasma were obtained before and after exercise stress from 18 patients who demonstrated inducible ischemia (cases) and 18 of whom did not (control). Lactic acid and metabolites involved in skeletal muscle adenosine monophosphate (AMP) catabolism increased after exercise in both cases and controls. Statistically

significant change in six members of the citric acid pathway were found in myocardial ischemic group but remained unchanged in controls.

Metabolomic studies of adipose tissues have been demonstrated to be useful in discovery of new biomarkers related to CVD. Several hormones and factors produced in this tissue have been associated with obesity, insulin resistance, and CVD, particularly, the accumulation of visceral adipose tissue increases the risk of developing metabolic disease and CVD [69]. In addition, alteration in lipid metabolism has been linked to several diseases such as atherosclerosis, diabetes, obesity, and stroke [69,71]. Altered lipoprotein particle composition has been detected by NMR in patients with hypertension [68].

21.9 LIPID-LOWERING AGENTS

21.9.1 Statins

Statins (3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors) are widely used and well-tolerated drugs in the treatment of hypercholesterolemia, lowering the risk of CVD. However, myopathy is a potential adverse effect of these agents. Cerivastatin was withdrawn from world markets as a result of the relatively high rate of fatal rhabdomyolysis that raised concerns on the safety of statins [72]. The mechanism of statin-caused myopathy is unclear; however, it appears to be dose dependent, the risk increases significantly when high dose is used and in particular when statins are prescribed in combination with agents that are also myotoxic or that increase the plasma concentration of statins [73,74]. Statins are highly selective inhibitors of HMG-CoA reductase inhibitors, showing almost no relevant affinity toward other enzymes or receptors [75], making pharmacodynamic interaction less likely. Clinically significant DDIs with statins are thought to result from altered clearance and distribution of statins. It was reported that the rate of myopathy is twofold greater (0.22%) in statin combination therapy with potential inhibitors than statins alone (0.12%) [76].

21.9.1.1 Drug Interaction by CYP Enzymes. Drug-specific interactions with each statin are dependent on metabolic pathway of individual statins (Tables 21.2 and 21.3). Simvastatin and lovastatin are administered as lipophilic lactone prodrugs, whereas other statins are given as active acid forms. Simvastatin, lovastatin, and atorvastatin are predominantly metabolized by CYP3A4 [77–79] and fluvastatin is metabolized primarily by CYP2C9 and to a lesser extent by CYP2C8 and 3A4 [80]. Rosuvastatin shows minimal metabolism, being excreted largely unchanged via the biliary route, and almost no meaningful pharmacokinetic interactions [81,82]. Pravastatin is partly degraded to 3/ α -isopravastatin and 6/ ϵ -epipravastatin in the stomach and partially metabolized by CYP enzymes or excreted as the parent compound into urine and bile [81].

Potent CYP3A inhibitors used with simvastatin or lovastatin significantly increased the exposure of these statins, probably a result of inhibited first-pass metabolism. Strong CYP3A inhibitors, such as itraconazole and ketoconazole, can increase the AUCs of simvastatin and lovastatin up to 20-fold [83–85]; however, only a slight AUC increase was observed with pravastatin, atorvastatin [86,87], rosuvastatin [88], and fluvastatin. Combination of saquinavir with ritonavir as a boosting agent increased AUC of simvastatin acid 30-fold; similarly, the AUC of atorvastatin was increased 3.5-fold [89].

TABLE 21.2 Pharmacokinetic Properties, Metabolizing Enzymes, and Transporters of Statins

Parameter	Simvastatin	Lovastatin	Atorvastatin	Fluvastatin	Pravastatin	Rosuvastatin	Pitavastatin
Lactone prodrug	Yes	Yes	No	No	No	No	No
Lipophilicity	+++	+++	+++	+++	+	++	+++
Absorption (%)	60–85	30	30	98	35	50	80
Bioavailability (%)	<5	5	12	30	18	20	60
Hepatic extraction (%)	≥ 80	≥ 70	70	≥ 70	45	63	—
Protein binding (%)	>95	>98	>98	>98	50	90	96
Half-life (h)	2–5	2–5	7–20	1–3	1–3	20	10–13
Metabolism	Extensive	Extensive	Extensive	Extensive	Mainly unchanged	Mainly unchanged	Limited
Metabolizing enzymes	CYP3A4, CYP2C8*	CYP3A4	CYP3A4, CYP2C8*, UGT*	CYP2C9, CYP3A4*, CYP2C8*	CYP3A4*	CYP2C9, CYP2C19*, CYP3A4*	CYP2C9*
Uptake transporters	OATP1B1	OATP1B	OATP1B1, OATP2B1	OATP1B1*, OATP1B3, OATP2B1	OATP1B1, OATP1B3, OATP2B1	OATP1B1, OATP1B3, OATP2B1	OATP1B1, OATP1B3, OATP2B1
Efflux transporters	PGP, BCRP (lactone)	PGP	PGP, BCRP	BCRP	BCRP, PGP, MRP2	BCRP, MRP2	BCRP*, PGP, MRP2

Cyclosporine	155, 696	406	645	89–254	1077, 2183	608	351
Grapefruit	37–1513	91, 1426	—	—	—	—	—
Gemfibrozil, fenofibrate	43	—	24	—	22–102	88	25, 36
PI or PI combination	507	—	74–836	—	90	36–212	31

Data collected from drug interaction database (University of Washington).

Grapefruit juice, an intestinal CYP3A4 inhibitor, can increase lovastatin and simvastatin AUC up to 15-fold and atorvastatin by 3.3-fold but no change for pravastatin. The extent of interaction depends on the amount of grapefruit juice; <1 quart daily consumption appears to have minimal effect [90]. Weak or moderate CYP3A4 inhibitors, such as verapamil, diltiazem, erythromycin, and clarithromycin, increase the AUC of simvastatin acid by about three- to ninefold [87,91]. There are few reports of clinically relevant DDI between fluvastatin and CYP2C9 inhibitors, even potent CYP2C9 inhibitor fluconazole appears to only slightly increase the plasma concentration of fluvastatin [92]. CYP2C8 contributes to the metabolism of simvastatin and lovastatin acid. Gemfibrozil and its glucuronide metabolites are CYP2C8 inhibitors. Gemfibrozil markedly increase the AUCs of the active simvastatin acid and lovastatin acid [93,94]. Generally, induction-mediated statin interaction is less clinically significant than that caused by potent inhibitors. CYP and transporter inducers, such as rifampin and carbamazepine, reduced the AUCs of simvastatin by 80–90% [95,96], rifampicin decreased fluvastatin by 50% and that of pravastatin by 30% [80,97].

21.9.1.2 Drug Interaction by Transporters. Many statins are substrates of efflux or uptake transporters expressed in the intestine and liver, for example, PGP, MRP2, bile salt export pump (BSEP), BCRP, OATP1B1, OATP1B3, and OATP2B1 (Table 21.2). Since most statins are eliminated by metabolism or biliary excretion, their active hepatic uptake, metabolism, and biliary excretion can regulate their total clearance. The interplay between intracellular CYP3A4 and the efflux transporter PGP in the intestinal wall may contribute to the high presystemic extraction of simvastatin and lovastatin, as well as mediate DDI [55].

The significance of BCRP in the pharmacokinetics of different statins has been shown in several studies [98,99]. Individuals with ABCG2c.421AA variant allele showed AUCs 70–144% higher for atorvastatin, rosuvastatin, fluvastatin, and simvastatin than mean AUC values for individuals with the c.421cc genotype.

OATP1B1, 1B2, and 1B3 are expressed on the sinusoidal membrane of hepatocytes and can facilitate liver uptake of their substrate drugs. All statins are OATP1B1 substrates; some are also substrates of other uptake transporters. OATP1B1 appears to be the most important liver-specific uptake transporter of statins [100]. It is believed that OATP1B1 inhibitors decrease the liver uptake of statins and increase plasma to liver concentration ratio, potentially leading to increased risk of skeletal muscle toxicity and attenuated cholesterol-lowering effect. In addition, genetic variability in the gene encoding OATP transporter can result in marked interindividual differences in pharmacokinetics. In one study, SLCO1B1c.521CC participants had a 91% and 74% larger pravastatin AUC than those with the c.521TT or c.521TC genotype, respectively [101]. The plasma concentrations of active simvastatin acid, pitavastatin, atorvastatin, and rosuvastatin have been 221%, 162%, 144%, and 65% higher in c.521CC homozygotes than c.521TT homozygotes; however, no significant effect was observed for fluvastatin [100].

Several drugs including cyclosporine, rifampicin, clarithromycin, and ritonavir act as OATP1B1 inhibitor *in vitro*. Cyclosporine is a potent OATP1B1 inhibitor ($K_i = 0.242 \mu M$), it also inhibits several influx and efflux transporters, such as OATP1B3, OATP2B1, MDR1, MRP2, and CYP3A4. Cyclosporine causes a 2- to 20-fold increase in AUC values of statins in organ transplant patient [102–109]. Since fluvastatin, pitavastatin, pravastatin, and rosuvastatin are not significantly

metabolized by CYP3A4, plasma concentration increases in these statins may be primarily due to OATP1B1 inhibition. A study by Bergman *et al.* [110] in pigs explored the mechanism of cyclosporine–rosuvastatin interaction. Intravenous infusion of cyclosporine markedly decreased the hepatic extraction of a single intrajejunal rosuvastatin dose, causing a 9.1-fold increase in AUC in hepatic vein with a 2.1-fold decrease in bile exposure. It was concluded that strong effect of cyclosporine resulted from the inhibition of OATP1B1-mediated sinusoidal transport, rather than canalicular transporters.

21.9.2 Gemfibrozil

Gemfibrozil [5-(2,5-dimethylphenoxy)-2,2-dimethyl-pentanoic] is an oral lipid-lowering agent, which is classified as a fibric acid derivative. Gemfibrozil decreases serum triglycerides, very low density lipoprotein, and increases high density lipoprotein cholesterol.

Gemfibrozil is completely absorbed after oral administration in human [111]; ~70% of an orally administered dose is excreted in urine, mostly as glucuronide conjugates, with <2% excreted as unchanged gemfibrozil. Six percent of the dose is accounted for the feces. Three major metabolic pathways of gemfibrozil were characterized. The first metabolic pathway is oxidation of *meta*-methyl group, yielding a benzyl alcohol that is further oxidized to benzoic acid metabolite. The second pathway is the hydroxylation of aromatic ring to phenol. The third pathway is glucuronide conjugation of gemfibrozil and its oxidative metabolites. Mano *et al.* [112] demonstrated that UGT2B7 is the primary isozyme responsible for gemfibrozil glucuronidation, although other UGT isoforms such as UGT1A1, 1A3, 1A9, and 2B15 also possess catalytic activity [113]. Also, Ogilvie *et al.* [58] showed human liver microsomes and recombinant CYP2C8 both convert gemfibrozil glucuronide to a hydroxylated metabolite. Gemfibrozil is shown to be a CYP2C9 inhibitor (IC_{50} of $30\ \mu M$), whereas its glucuronide was found to be a more potent mechanism-based CYP2C8 inhibitor (IC_{50} of $1.8\ \mu M$). Coadministration of gemfibrozil with the CYP2C9 substrate warfarin does not increase the plasma concentrations of warfarin [114]. However, gemfibrozil can increase the plasma concentration of CYP2C8 substrates. The AUCs of antidiabetic agents rosiglitazone and pioglitazone and μ -opioid receptor agonist loperamide were increased to over twofold [115–118] and the AUC of repaglinide can be increased up to eightfold [26,27].

In addition, gemfibrozil caused a sixfold increase in the mean AUC value of cerivastatin [119] and moderate AUC increase in active simvastatin acid [93], lovastatin acid [94], atorvastatin [120], pravastatin [121], and rosuvastatin [122]. Gemfibrozil–statins interaction may be based on the dual inhibition of both OATP1B1 and CYP2C8; the extent of interaction may depend on the relative importance of OATP1B1 and CYP2C8 in the pharmacokinetics of the statin. Gemfibrozil and its 1-*O*-glucuronide appear to be relatively weak inhibitors of OATP1B1 ($K_i \sim 22\text{--}25\ \mu M$) [123]. *In vitro* experiments showed that gemfibrozil ($200\ \mu M$) reduced OATP1B1-, 2B1-, and 1B3-mediated fluvastatin transport from 62% to 97% [124].

Combination treatment of statins and fibrates is a potentially useful strategy to improve lipid and lipoprotein profiles and reduce cardiovascular risk in patients with diabetes mellitus and metabolic syndrome. However, statin–fibrate combination regimens have potential adverse effects on skeletal muscles including myopathy. The

mechanism of statin-related or statin-fibrate-related muscle toxicity are not clear, may result from both pharmacodynamic and pharmacokinetic mechanism [125]. Since other fibrates, such as fenofibrate and bezafibrate, do not have significant effects on OATP1B1, and CYP2C8 showed only minor pharmacokinetic interaction [126], it is expected that treatment with fenofibrate in combination with statin might be less likely to cause adverse muscle effects than gemfibrozil–statin regimes on the base of pharmacokinetic interaction.

21.10 DIURETICS

The loop diuretic torsemide is well absorbed and yields a bioavailability of 80% in healthy individuals [127]. Torsemide undergoes extensive hepatic metabolism, only 20% of the parent drug is recovered unchanged in the urine. The major portion of renal excretion of torsemide occurs via tubular secretion. Renal failure seems to have minimal effect on total plasma clearance, whereas ~50% decrease in plasma clearance was observed in patients with liver disease and an increase in elimination half-life. Hydroxylation of the methyl group of the phenyl ring, M1, and further oxidized metabolite, M5 (carboxylic acid), are major metabolite detected in urine. The metabolite M5 is pharmacologically inactive, metabolite M1 may be ~10% as active as the parent drug. M1 formation is primarily mediated by CYP2C9 with an apparent K_m value of 11–23 μM [128]. CYP2C8 contributed the M1 formation to a minor extent [129]. A clinically significant drug interaction of torsemide involving the CYP450 system has not been reported.

Thiazide diuretics, indapamide and xipamide, undergo extensive hepatic metabolism; however, the underlying enzymes are poorly characterized [130]. Other loop diuretics, such as furosemide, bumetanide, ethacrynic acid, and thiazide diuretics, including chlorothiazide, cyclothiazide, hydrochlorothiazide, and trichlormethiazide, are primarily eliminated in urine via tubular secretion. These diuretics, which carry a common chemical characteristic of a sulfamoyl group, are weak organic acids. It has been reported that organic anion transporters are involved in the tubular secretion of diuretics [131]. OAT1 is suggested to play an important role in the basolateral uptake of thiazides, whereas OAT3 is mainly responsible in the uptake of loop diuretics, it is also suggested that bumetanide taken up by OAT3 and/or OAT1 is excreted into the urine by OAT4. In rats, OAT1 contributed to the renal tubular secretion of thiazides and loop diuretics [132].

Concomitant administration of probenecid and furosemide results in a ~2.5-fold increase in furosemide AUC [133] and 60% decrease in furosemide oral clearance, suggesting probenecid inhibits furosemide secretion, probably by the organic anion transporter (OAT) system.

21.11 ANTITHROMBOTICS

21.11.1 Warfarin

A widely prescribed oral anticoagulant for the treatment and prevention of thrombotic diseases, warfarin has a narrow therapeutic range and a >10-fold interindividual variability in the dose required to attain a therapeutic response [134]. The most common

adverse event associated with warfarin overdose is bleeding. Warfarin initiation doses are often prescribed empirically and typically range from 2.5 to 10 mg/day with peak effects usually observed after ~5 days [135]. It usually takes several weeks to establish a patient's optimal maintenance dose by intense International Normalized Ratio (INR) monitoring and dose adjustments based on multiple influencing factors, such as diet, disease state, concomitant use of other medications, and genetic factors. At least 30 genes have been associated with the metabolism and action of warfarin [136]; single nucleotide polymorphisms in CYP2C9 and VKORC1 are strongly associated with warfarin dose requirements [134,135,137]. In August 2007, the FDA revised the prescribing information for warfarin to encourage, but not require, pharmacogenomics testing when initiating warfarin therapy [138].

Warfarin tablets contain a racemic mixture of R- and S-isomers. The S-isomer exhibits three to five times more anticoagulant activity than the R-isomer in humans. Under steady-state conditions, S-warfarin accounts for 60–70% of warfarin anticoagulant effect and R-warfarin for 30–40% [139]. Warfarin is completely absorbed after oral administration with peak concentration generally attained within the first 4 h. Elimination of warfarin is almost entirely by metabolism. The warfarin isomers undergo stereoselective metabolism; S-warfarin is metabolized primarily by CYP2C9 to 7-hydroxywarfarin, R-isomer is metabolized primarily by CYP1A2 to 6- and 8-hydroxywarfarin, by CYP3A4 to 10-hydroxywarfarin, and by carbonyl reductase to diastereoisomeric alcohol [14]. CYP2C9 tends to have more clinical significance than CYP3A4 or carbonyl reductase. Two common variants CYP2C9*2 and *3 have 12% and 5% reduced catalytic activity compared to wild type (*1) [136]. A systematic review and meta-analysis of nine studies has showed that patients carrying at least one variant allele of CYP2C9*2 have a 17% reduction of daily warfarin dose and a 37% reduction of daily warfarin dose for patients carrying CYP2C9*3 [140]. Patients carrying at least one copy of variant alleles have a increased relative risks of bleeding as compared to wild type (relative risk of 1.9 for CYP2C9*2 and 1.77 for CYP2C9*3).

Vitamin K epoxide reductase (VKOR) is involved in making vitamin K-dependent clotting factors and is the target enzyme for warfarin. Multiple variants in the genes encoding VKOR have been identified and also correlate with warfarin dose requirements. Several studies suggest that variations in CYP2C9 and VKOR can potentially account for 5–22% and 6–37% of the interindividual variability of warfarin dose [134]. A pharmacogenetic algorithm was developed by the International Warfarin Pharmacogenetics Consortium using genotypes from VKORC1 and CYP2C9 and clinical variables to predict the stable therapeutic dose [141]. The data are from a large and diverse cohort of patients (4043 patients) and validation cohort (1009 patients). The algorithm appears to predict the stable therapeutic dose of warfarin better than a fixed dose approach and better than a clinical algorithm built from the same large data set. The pharmacogenetic was more accurate at identifying patients who required low doses (21 mg or less per week) and those requiring high doses (49 mg or more per week). In January 2010, the FDA updated the warfarin label specifying that “a patient's CYP2C9 and VKORC1 genotype information when available, can assist in selection of the starting dose.” The agency also provides initial dosage recommendations for patients with different variant combinations. However, the FDA does not require that genetic testing be done before prescribing warfarin.

21.11.2 Antiplatelet Drugs

Coronary artery disease, one of the leading causes of mortality in the United States, can be effectively managed by administration of various antithrombotic strategies. The most widely used is treatment with one of several antiplatelet regimens. There are three marketed thienopyridine antiplatelet prodrugs that function by inhibition of ADP P2Y₁₂, resulting in diminished platelet aggregation and lessened risk of thrombosis.

The thienopyridine ticlopidine, clopidogrel, and prasugrel are prodrugs that require biotransformation to produce their respective active metabolites. Ticlopidine is the first compound of this class, introduced to the market in 1979 for prevention of thrombotic stroke. After a single oral dose of [¹⁴C]ticlopidine to human, about 60% of the administered radioactivity was recovered in the urine and 23% in the feces [142,143]. 2-Chlorohippuric acid was the main metabolite detected in urine, whereas ticlopidine was present in trace amount in urine. Other lower level metabolites such as 2-oxo-ticlopidine, ticlopidine-*N*-oxide, and *o*-chlorohippuric acid were also detected. The pharmacologically active metabolite was not detected or identified. The structure of the active metabolite was first deduced based on the structures of prasugrel and clopidogrel active metabolites and later on characterized after *in vitro* incubation of 2-oxo-ticlopidine with homogenates prepared from phenobarbital-induced rat livers [144]. CYP2C19 and 2B6 were shown to contribute to the formation of 2-oxo-ticlopidine [145,146]; however, the CYPs involved in the metabolic transformation of 2-oxo-ticlopidine to active metabolite are unknown.

Ticlopidine is dosed at 250 mg BID and although generally safe is characterized by a number of side effects, including gastrointestinal disturbances, skin rash, and in rare cases hepatotoxicity, agranulocytosis, neutropenia, and aplastic anemia [143,147]. The later could be due to formation of reactive metabolites and high dose [147,148]. Clopidogrel and prasugrel were introduced at much lower dose of 75 and 10 mg QD and are characterized by generally better safety.

Metabolism of clopidogrel proceeded with two competitive pathways with the primary pathway leading to the formation of inactive acid metabolite by carboxylesterase I (hCE1) [149,150]. The minor pathway proceeded with the formation of 2-oxo-clopidogrel, an intermediate to further ring opening active metabolite. Several studies suggested CYP1A2, 2B6, and 2C19 contribute to 2-oxo-clopidogrel formation; the active metabolite was formed from the thiolactone by CYP2B6, 2C9, 2C19, and 3A4. Several clinical trials have shown that efficacy of clopidogrel is associated with CYP2C19 functionality such that subjects who were carriers of the reduced-function CYP2C19 allele showed significantly poorer clinical response and lower AUC of active drug [143]. The FDA has added a black-box warning to the clopidogrel label, indicating that mutations in the CYP2C19 gene render certain patients unable to respond to the drug, which places them at increased risk for heart attack and stroke.

Prasugrel is the newest thienopyridine antiplatelet drug approved for use in Europe and the United States for the reduction of thrombotic cardiovascular events in patients with acute coronary syndrome, who are to be managed with PCI. Prasugrel is rapidly absorbed and extensively metabolized such that it is not detected in plasma. It is rapidly hydrolyzed by hCE2, primarily an intestinal enzyme, to form the thiolactone, which is further metabolized to the active metabolite primarily by CYP3A4 and 2B6 and to a lesser extent by CYP2C9 and 2C19 [143]. The active metabolite is the major metabolite circulating in plasma, representing 26% of the AUC_{0–12h} of the radioactivity [143].

In vitro, ticlopidine was a potent mechanism-based inhibitor of CYP2C19 slowing the clearance of omeprazole and phenytoin, resulting in toxicity of the latter [151]. Clopidogrel showed similar though less pronounced inhibition of CYP2C19 and both drugs showed inhibition of CYP2B6 [146]. Prasugrel did not meaningfully inhibit either isoform due to its activation via noncup processes. This series of drugs presents an illustrative example of progressive drug discovery.

21.12 ANTIARRHYTHMICS

Antiarrhythmic agents are a group of pharmaceuticals that are used to suppress fast rhythms of the heart such as atrial fibrillation, atrial flutter, ventricular tachycardia, and ventricular fibrillation. Antiarrhythmic drugs comprise many different drug classes with different mechanisms of action. The Vaughan–Williams classification is one of the most widely used classification schemes for antiarrhythmic agents. This classification scheme is based on the primary mechanism of its antiarrhythmic effect. There are five main classes in the Vaughan–Williams classification of antiarrhythmic agents. Class I agents interfere with the sodium channel, class II agents are β -blockers, class III agents affect potassium efflux, class IV agents affect calcium channel and the atrioventricular (AV) node, and class V agents work by other or unknown mechanisms.

21.12.1 Class I Agents

Quinidine is the oldest clinically used antiarrhythmic agent. In human liver microsomes, two major metabolites of quinidine are identified: (3*S*)-3-hydroxy-quinidine (3-OH-Q) and quinidine-*N*-oxide (Q-N-OX) [152]. Formation of 3-OH-Q is mediated exclusively by CYP3A4 with the K_m value of $74\mu M$. CYP3A4 is also a primary enzyme catalyzing Q-N-OX formation with a K_m of $76\mu M$; CYP2C9 and 2E1 catalyze minor proportions of the N-oxidation. *in vivo* studies to assess the effect of diclofenac, disulfiram, itraconazole, grapefruit juice, erythromycin, and fluvoxamine on the pharmacokinetics of quinidine confirm the important role of CYP3A4 in the oxidation of quinidine *in vivo*, particularly in the formation of 3-OH-Q [153,154]. It has been suggested that the formation of 3-OH-Q may serve as an indicator of CYP3A4 activity *in vivo* [155]. Quinidine is also a potent competitive CYP2D6 inhibitor with K_i value in the range of $0.027\text{--}0.4\mu M$ and a PGP substrate with an efflux ratio of 3 in caco2 assay [156].

Quinidine has been involved in numerous DDIs. Coadministration of quinidine with cimetidine, itraconazole, verapamil, and diltiazem led to a moderate increase in quinidine plasma concentration and a 30–60% decrease in total plasma clearance. The effect appears to be mediated through inhibition of CYP3A4 and/or inhibition of renal tubular secretion of the parent drug [157–160]. Plasma concentration of quinidine can be significantly decreased by CYP inducers such as rifampicin, phenytoin, and phenobarbital [161]. Coadministration of metoprolol, a CYP2D6 substrate, with quinidine resulted in a fivefold increase in the metoprolol AUC [162]. Similar quinidine cotherapy with dextromethorphan led to a 40-fold increase in AUC values of dextromethorphan, a CYP2D6 substrate [163]. Quinidine was associated with >threefold increases in plasma digoxin concentrations when coadministration with quinidine. Several studies suggested that inhibition of PGP-mediated digoxin efflux by quinidine leading to

increased absorption and decreased renal and biliary clearance may be the underlying mechanism [98,164].

Procainamide is an antiarrhythmic medication that is primarily used to treat ventricular tachydysrhythmias. Oral doses of procainamide are rapidly and nearly completely absorbed [165]. At therapeutic doses, 48% of dose is excreted unchanged in urine. *N*-acetyl procainamide (NAPA) was the major metabolite in the urine (15% of the dose). The $C_{\max}$ of NAPA was 50% of that of procainamide in the 10 human subjects; however, plasma concentration of NAPA was higher than that of procainamide in 2 patients. The formation of NAPA was mainly mediated by the cytosolic polymorphic NAT. The NAPA to procainamide ratios in urine and plasma were found to be higher in rapid than in slow acetylators [166–168]. Genetic variant NAT2*4, NAT2*6A, and NAT2*7B were shown to metabolize procainamide with K_m values in the range of 2–3 mM [169]. NAPA is an active metabolite with ~70% of the antiarrhythmic activity of the parent drug [170]. It is important to consider both procainamide and NAPA levels when evaluating the status of a patient. In addition to *N*-acetylation, Uetrecht and coworkers [171] demonstrated that procainamide was metabolized to the reactive *N*-hydroxylamine-procainamide (NOH-PA), further formed highly reactive nitroso procainamide (NO-PA), NO-PA may covalently bind to macromolecules, leading to the drug-induced lupus erythematosus syndrome observed during the procainamide chronic therapy. *In vitro* chemical inhibition and correlation analysis suggested that CYP2D6 was the major human CYP isozyme involved in the formation of the reactive metabolite of procainamide, namely, *N*-hydroxyprocainamide [172]. It was reported that coadministration with amiodarone, antibacterials trimethoprim and ofloxacin, propranolol, and cimetidine increased the plasma concentration of procainamide and NAPA [161].

Lidocaine is a widely used local anesthetic and antiarrhythmic drug that undergoes extensive metabolism in the liver [173,174]. Following a single oral dose of 250 mg to two healthy volunteers, the major urinary metabolite was 4-hydroxy-2,6-dimethylaniline and its conjugating metabolites (72% of the dose). Monoethylglycinexylidide (MEGX) and other aromatic hydroxylated metabolites represented <5% of the dose in urine. In human liver microsomes, lidocaine was mainly oxidized to *N*-deethylated metabolite, MEGX, whereas 3-hydroxylation on the aromatic ring was a minor metabolic pathway [175]. Both CYP1A2 and 3A4 were capable of catalyzing the formation of MEGX and 3-hydroxyl lidocaine [93], CYP1A2 was the major isoform catalyzing lidocaine *N*-deethylation at low substrate concentration (5 μM), CYP3A4 contributed more at higher lidocaine concentration (800 μM), and 3-hydroxylation was primarily catalyzed by CYP1A2. MEGX appeared to have similar antiarrhythmic and convulsant activities to lidocaine and may be synergistic to the effectiveness and toxicity of lidocaine [176]. CYP3A4 inhibitors, erythromycin and itraconazole, increased lidocaine peak plasma concentration by 40–70% [177]. Isohanni and coworker [178] further studied the effect of fluvoxamine (CYP1A2 inhibitor) and erythromycin on the pharmacokinetics of lidocaine, fluvoxamine alone increased the mean AUC of lidocaine to 305% and the $C_{\max}$ to 220% compared to the placebo phase, but there was no significant effect on the $T_{\max}$ or half-life of lidocaine. The combination of fluvoxamine and erythromycin increased the mean AUC of lidocaine to ~360% and the $C_{\max}$ of lidocaine to 250%. It was concluded that inhibition of CYP1A2 by fluvoxamine considerably reduces the presystemic metabolism of oral lidocaine and may increase the risk of lidocaine toxicity if lidocaine is ingested. Lidocaine disposition is significantly affected by changes in hepatic blood flow [179]. β -Blocker propranolol has

been shown to decrease lidocaine clearance secondary to decreased hepatic blood flow [161], subsequently elevated lidocaine plasma concentration has been associated with central nervous system (CNS) toxicity. Similar interaction may be expected with other β -blockers since most appear to decrease hepatic blood flow. In addition, coadministration with amiodarone, cimetidine, and HIV protease may also alter plasma concentration of lidocaine.

Propafenone is a class 1C antiarrhythmic drug with local anesthetic effects and a direct stabilizing action on myocardial membranes. The metabolism of propafenone was studied in human after a single oral dose [180]. Propafenone is completely absorbed and metabolized, <1% of the dose was recovered as parent drug. The major metabolites in excreta are conjugates of 5-hydroxypropafenone (5-OH-PF) and hydroxy-methoxypropafenone and propafenone glucuronide. Conjugates of hydroxylated derivatives of propafenone are predominant components in the plasma. Propafenone is administered as a racemate of *S*(+)- and *R*(-)-enantiomers. (*R,S*)-propafenone was mainly metabolized to 5-OH-PF and *N*-dealkylated propafenone (NDPF) in human liver microsomes [181]. The formation of 5-OH-PF is primarily mediated by CYP2D6; CYP3A4 and 1A2 mediated the formation of NDPF. The 5-OHPF formation from racemic propafenone and from its individual enantiomers followed one-enzyme Michaelis–Menten kinetics with a mean K_m of 0.12 μM . Stereoselectivity in V_{max} and K_m values was observed, with (*S*)-propafenone displaying higher K_m and V_{max} values. *N*-Depropylpropafenone (*N*-DPP) was monophasic with a mean K_m of 116 μM . No stereoselectivity in propafenone *N*-dealkylation was observed [182]. Large interindividual variations in plasma concentration observed in human can be explained by genetically determining metabolism of propafenone via CYP2D6. A clinical study in 28 patients with chronic ventricular arrhythmias (22 extensive metabolizers (EMs) and 6 poor metabolizers (PMs)) concluded that propafenone metabolism was polymorphic and cosegregated with that of debrisoquine 4-hydroxylation [183]. The data also suggested that PMs are at higher risk of developing CNS side effects presumably due to the high plasma concentration achieved in these patients. Therefore, monitoring of the plasma concentration of propafenone may be clinically useful for the prediction of CNS side effects. It was proposed to use urinary excretion of intact glucuronides of propafenone to determine the metabolic phenotype of propafenone [184]. Propafenone is also a potent CYP2D6 competitive inhibitor with a K_i value of 34 nM [185] and a weak CYP1A2 inhibitor with the K_i value of 21 μM [186]. Moreover, propafenone was not a substrate of PGP, whereas propafenone and its metabolites 5-OH-PF and NDPF inhibited PGP-mediated digoxin transport with IC_{50} values of 6.8, 19.9, and 21.3 mM, respectively, therefore contributing to the digoxin–propafenone interaction observed in human [161,187–189]. Propafenone increased the plasma concentration of metoprolol, propranolol, mexiletine, and warfarin [141,190–192] and led to adverse effects. Thus, the dose of these drugs should be adjusted when coadministration with propafenone.

21.12.2 Class II Agents: β -Adrenergic Blockade

β -Adrenoreceptor blockers are widely prescribed for the treatment of CVD, including hypertension, coronary heart disease, and heart failure. Over 30 agents are available worldwide and are distinguished by the presence of β_1 selectivity, partial agonism, membrane stabilizing effect, the presence of β -receptor antagonism, direct vasodilating

properties, and so on. From a pharmacokinetic perspective, these drugs can be divided into two general categories [193]: those primarily metabolized by the liver and those that are predominantly excreted unchanged by the kidney. The former include propranolol, metoprolol, carvedilol, and so on and the latter include atenolol, nadolol, sotalol, and so on.

Carvedilol is metabolized primarily to glucuronide conjugates in human (22% of total plasma radioactivity and 32% of total urine radioactivity) [194,195]. Three UGT isoforms including UGT1A1, 2B4, and 2B7 can catalyze the reaction with similar K_m values in the range of 20–50 μM [196]. Stereoselective metabolism of racemic carvedilol by UGT1A1 and 2B7 was observed [197]. Oxidative metabolites 4 or 5-hydroxy carvedilol were also observed in urine with a small portion of dose (6.4%). CYP2D6 was mainly involved in the formation of these two oxidative metabolites [198]. A clinical study evaluating the effects of polymorphisms in UGTs and CYP2D6 on pharmacokinetics of carvedilol in Japanese suggested that genetic polymorphisms of UGT2B7 and CYP2D6 may be partially responsible for interindividual variation in carvedilol clearance [199].

Propranolol is cleared almost entirely by metabolism with <1% of the dose recovered as unchanged drug [200]. The drug is metabolized through three primary pathways: direct glucuronidation (17% of dose), aromatic hydroxylation (mainly 4-hydroxylation, 42% of dose), and side-chain oxidation. Four major metabolites are characterized as propranolol glucuronide, naphthyloxylactic acid, glucuronide, and sulfate conjugates of 4-hydroxyl propranolol. *In vitro* studies indicate that CYP2D6 is the predominant propranolol 4-hydroxylase; however, CYP1A2 may also significantly contribute propranolol 4-hydroxylation, especially in the 2–10% of the Caucasians who are poor metabolizers of CYP2D6 [201]. Both CYP1A2 and 2D6 catalyze the side-chain oxidation [202]. UGTs 1A9, 1A10, 2B4, and 2B7 catalyze propranolol glucuronidation [203]. On average, the contribution of CYP2D6 to the overall elimination of propranolol is insufficient to cause differences in its pharmacokinetics between phenotypes [204]. However, coadministration of several CYP2D6 inhibitors, such as quinidine, propafenone, or fluoxetine, resulted in significant increases in propranolol plasma level and altered the clinical response [190,205,206]. Rifampicin is a potent inducer of propranolol metabolism, resulting in two- to fourfold increase in propranolol clearance [207,208]. Propranolol is also an inhibitor of CYP2D6 and 1A2, the major isoforms catalyzing its metabolism. Coadministration with theophylline (CYP1A2 probe substrate) resulted in the increased plasma level of these drugs [209].

Metoprolol undergoes extensive hepatic metabolism with <5% of the dose recovered unchanged in urine [210]. Three major metabolic pathways were identified: O-desmethylation (65% of dose), deamination (10% of dose), and α -hydroxylation (10% of dose). CYP2D6 phenotype has a significant effect on metoprolol plasma concentration with PMs having sixfold higher steady-state concentration than EMs [204,211]. Coadministration of CYP2D6 inhibitors profoundly affects metoprolol plasma level and may result in phenotype change from EM to PM. Quinidine coadministration causes a 60% decrease in metoprolol plasma clearance [212], paroxetine increased mean metoprolol AUC about fourfold [213]. Although the expected effects of CYP2D6 genotype on pharmacokinetics of metoprolol were observed, the effect of CYP2D6 genotype on efficacy and toxicity of metoprolol is controversial, most studies suffer from small numbers of CYP2D6 PMs [204,214]. A recent clinical study with 1533 patients demonstrated metoprolol subject homozygous for the CYP2D6*4 allele had a significantly

lower heart rate and diastolic blood pressure than those with the wild-type genotype [214].

21.12.3 Class III Agents: Potassium Channel Blockade

Class III antiarrhythmic drugs, including amiodarone, bretylium, dofetilide, ibutilide, and sotalol, are effective for the management of various types of cardiac arrhythmias both atrial and ventricular in origin. Among the class III antiarrhythmic drugs, bretylium and sotalol are primarily excreted unchanged in urine. Ibutilide is extensively metabolized in the liver to primarily ω -oxidative metabolites followed by sequential β -oxidation of the heptyl side chain of ibutilide. These reactions are not mediated by CYP3A4 and 2D6, but possibly by CYP4 families. No significant pharmacokinetic drug interactions for these agents have been identified [161,215]. Dofetilide is mainly cleared in the kidney via the cationic transport system. Cimetidine, ketoconazole, trimethoprim, prochlorperazine, megestrol, and thiazide diuretics can inhibit tubular secretion. Thus, drugs that inhibit CYP3A4 and/or the renal transport system may interact with dofetilide [215].

Amiodarone has a large volume of distribution and is distributed extensively to extravascular tissues such as liver, lung, and adipose [216]. High dose amiodarone has been associated with pulmonary toxicity. A recent study suggests that amiodarone is a OATP2B1 substrate and that amiodarone uptake via OATP2B1 might lead to accumulation of amiodarone in the lung and amiodarone-induced pulmonary toxicity [186]. Amiodarone undergoes extensive metabolism in the liver, the primary and principle metabolite is desethylamiodarone [217], this metabolite is found to parallel amiodarone concentration in plasma but has variable concentration in tissues. Desethylamiodarone has higher concentration than that of amiodarone in most tissues but lower concentration in adipose. Desethylamiodarone may also contribute to amiodarone-induced pulmonary toxicity. Desethylamiodarone metabolite is pharmacologically active and may be synergistic to the pharmacological effect of amiodarone [176]. Multiple CYP enzymes including CYP1A1, 3A4, 1A2, 2D6, 2C8, and 2C19 catalyzed amiodarone N-deethylation. However, CYP2C8 and 3A4 were significantly involved in amiodarone N-deethylation in human liver microsomes. CYP2C8 has been suggested to be a predominant isoform at clinically relevant concentrations of amiodarone [218,219]. Amiodarone weakly inhibits CYP2C9, 2D6, and 3A4 with K_i values of 45–271 μM . Desethylamiodarone inhibits CYP2D6, 2A6, 2B6, 1A1, 1A2, 2C9, and 2C19 with lower K_i values of 2.3–15.7 μM [220]. Amiodarone and desethylamiodarone markedly inhibited the basal–apical transport (renal secretion) of [3H]digoxin and increased the apical to basal transport (reabsorption) with IC_{50} of 5.48 and 1.27 μM , respectively. The clinically significant DDI between digoxin and amiodarone could be due to the increased digoxin bioavailability via inhibition of PGP present in the gastrointestinal tract [215,221]. Numerous drug interactions have been reported between amiodarone and other drugs. Coadministration with phenytoin, warfarin, and cyclosporine increases the plasma concentrations of these drugs through inhibitions of CYP2C9, 2C9 and 1A2, and 3A4, respectively [161,215]. The magnitude of interaction appears to be dependent on the dose of amiodarone. Plasma concentration of these drugs should be monitored and dosage adjusted accordingly. Other antiarrhythmic agents, such as dofetilide, flecainide, lidocaine, ibutilide, lidocaine, procainamide, and sotalol, showed drug interaction with amiodarone [215].

21.12.4 Class IV Agents: Calcium Channel Blockade

Verapamil is a class IV L-type calcium channel blocker of the phenylalkylamine chemical class. It has been used in the treatment of hypertension, angina pectoris, cardiac arrhythmia, and most recently, cluster headaches. Verapamil is administered as a racemic mixture of S- and R-enantiomers. The two enantiomers possess different pharmacokinetic and pharmacodynamic properties. The pharmacological properties (i.e., the negative dromotropic effect) are up to 20 times more potent for S-verapamil than R-verapamil [222]. In human, the metabolism of verapamil is stereoselective, the clearance of S-enantiomer is fourfold more rapid than that of R-enantiomer [223] after oral administration of racemic mixture. AUC ratio of R-verapamil to S-verapamil is ~ 5 . However, when administered intravenously, the AUC of S-verapamil is $\sim 50\%$ lower than that of R-verapamil [224]. Verapamil is extensively metabolized; only 3–4% of dose is excreted in urine as the unchanged drug [225]. N- and O-dealkylation are prominent metabolic pathways, producing a secondary amine (D-617) and norverapamil [226]. The N-dealkylation of verapamil in human liver microsomes is not stereoselective. CYP3A and 1A2 are the primary enzymes responsible for N-dealkylation and N-demethylation [227], whereas O-demethylation is mainly mediated by CYP2C family [228]. Grapefruit juice, a moderate CYP3A inhibitor, increases verapamil AUC by 40%; smokers had significantly lower AUC and $C_{\max,ss}$ values than nonsmokers by (means) 0.61- to 0.85-fold for verapamil and norverapamil enantiomers, respectively [229]. While the CYP3A inducer rifampin causes a 90% reduction in verapamil AUC, *in vitro* studies suggest that verapamil is a PGP substrate with an efflux ratio in the range of 2–5 [230–232]. Lovastatin and atorvastatin increase verapamil AUC by 40–60% in healthy Korean subjects, possibly via inhibiting both PGP and CYP3A [233,234]. Verapamil is a moderate CYP3A4, 2D6, 1A2, and 2C19 inhibitor *in vitro* [235–238]. Verapamil increases the AUCs of CYP3A4 probe substrates, midazolam, buspirone, and simvastatin by three- to fivefold [87,239,240]. Coadministration with verapamil only slightly increases theophylline AUC [241,242].

21.13 ACE INHIBITORS

ACE inhibitors are important therapies in the treatment of hypertension, congestive heart failure, postmyocardial infarction, and diabetic nephropathy. By inhibition of ACE, the drugs reduce angiotensin II synthesis in the circulation and tissues. The ACE inhibitors are currently classified into three classes based on their molecular structures. The first class represents sulfhydryl-containing agents, such as captopril (the first ACE inhibitor) and zofenopril. The second class, the dicarboxylate-containing agents, are the largest group including enalapril, lisinopril, ramipril, perindopril,trandolapril, quinapril, benazepril, imidapril, temocapril, spirapril, and moexipril. The third class represents phosphorus-containing inhibitors; fosinopril is the only member of this group.

Captopril is the first ACE inhibitor introduced to the market for the treatment of hypertension and congestive heart failure. After oral administration of captopril, $\sim 70\%$ of dose is absorbed with a bioavailability of 60% [203]. The compound is primarily cleared by urine. For patients with renal impairment, the dose may be reduced based on the degree of renal failure. The most common adverse effects associated with captopril use is skin rash, taste disturbance, neutropenia, and more severe forms of cutaneous

disorders, such as toxic epidermal necrolysis, lichenoid eruption, or pemphigus. The latter have been attributed both to a sulfhydryl substituent and overdosage [203,243]. Second-generation ACE inhibitors lacking the sulfhydryl group do not show the cutaneous adverse events. All dicarboxylate-containing agents except lisinopril are prodrugs designed to improve oral absorption from gastrointestinal tract and are metabolized by esterase in the liver and/or small intestine to the active components. CYP is not involved in the metabolism of ACE inhibitors. The predominant elimination pathway of most ACE inhibitors including enalapril, benazepril, quinapril, trandolapril, moexipril, and imidapril is via the kidney [203,244]. For other ACE inhibitors, such as fosinopril, ramipril, lisinopril, spirapril, and temocapril, the proportion of a dose recovered in feces increased. For most ACE inhibitors, AUC and elimination half-life increase by three- to sixfold in patient with $CL_{cr} < 30$ mL/min. A dose reduction is often recommended in patients with moderate to severe impairment of renal function. Dosage justification is not needed in patients with hepatic disease for most ACE inhibitors except for moexipril and spirapril. A 30–100% lower C_{max} and AUC were observed in patients with hepatic disease compared with healthy young volunteers.

Most ACE inhibitors resemble Ala-Pro dipeptide or Xaa-Ala-Pro tripeptide structures. It is known that di- and tripeptides are taken up into intestinal cells by the low affinity H^+ /peptide cotransporter PEPT1. In the kidney tubule, di- and tripeptides are reabsorbed by PEPT1 and by the high affinity H^+ /peptide cotransporter PEPT2 [245]. The involvement of PEPT1 and PEPT2 in the transport of ACE inhibitors is controversial. A recent investigation on the interaction of ACE inhibitors with PEPT1 and PEPT2 by Knutter and coworker suggests that most ACE inhibitors have low affinity with peptide transporters with the K_i values in the range of 0.3–3 mM; zofenopril and fosinopril show stronger affinity with K_i values of 13–30 μM . Further studies measuring transport current show low or no measurable electrogenic transport activity for all tested ACE inhibitors. Knutter *et al.* conclude that peptide transporters do not control intestinal absorption and renal reabsorption of ACE inhibitors. *In vitro* data suggests that enalapril is a substrate of OATP1B1/1B3 and MRP2 [246] and quinapril is a substrate of renal hOAT3 [247].

21.14 ANGIOTENSIN RECEPTOR BLOCKERS

The angiotensin receptor blockers (ARBs) are a group of antihypertensive drugs that act by blocking the effects of the hormone angiotensin II (Ang II) in the body, thereby lowering blood pressure. Their main indications are mild to moderate hypertension, chronic heart failure, and secondary stroke prevention and diabetic nephropathy. Saralasin, the first Ang II blocker, is an octapeptide analog of Ang II. This compound is not orally bioavailable, has short biological half-life, and shows partial agonist activity; therefore, it is not suitable as a drug [248]. However, early studies with saralasin provided the foundation for the therapeutic potential of Ang II receptor blockade. Great efforts by a group at DuPont and research investigators at Takeda focused on developing a smaller nonpeptide substance with similar binding affinity and acceptable oral bioavailability. The first successful Ang II blocker, losartan, was approved in 1995. Since then, five other ARBs including candesartan cilexetil, eprosantan, irbesartan, telmisartan, and valsartan and three combinations with hydrochlorothiazide (irbesartan, losartan, and valsartan) have been approved as antihypertensive agents. All ARBs

have a carboxylic acid group except for irbesartan. Candesartan cilexetil, a racemic prodrug, is rapidly and completely metabolized by esterase in the gastrointestinal tract to the active candesartan [249]. Candesartan is not metabolized by CYP system; after oral administration, candesartan is excreted mainly unchanged in feces via bile and in urine.

Losartan is rapidly and completely absorbed in healthy adult volunteers [250]. Losartan undergoes extensive first-pass metabolism with oral bioavailability of ~33%. It is converted to aldehyde intermediate E-3179 and further oxidized to a carboxylic acid metabolite (E-3174) that is responsible for most of the angiotensin II receptor antagonism. About 14% of an oral dose is converted to this active metabolite. *In vitro* and *in vivo* studies employing chemical inhibition, inhibitory antibody, and recombinant human hepatic CYP isoforms indicate that CYP2C9 is the predominant enzyme in losartan metabolism to its active metabolite D-3174 [251]. Relatively modest changes in the concentration of losartan and E-3174 were observed when the CYP2C9 inhibitor fluconazole [83,252] or inducer phenobarbital [12] was coadministered with losartan. Fluconazole decreased the E-3174 concentration by 70% and increased losartan AUC by 27%. Coadministration of phenytoin significantly reduced the oral clearance of losartan and AUC_(0–24) only in wild-type CYP2C9 individuals [245]. This result suggests that DDI studies with losartan should be evaluated in the context of CYP2C9 genotype of the study subjects. Losartan is a PGP substrate [253]; however, it does not alter pharmacokinetics of digoxin [254]. To date, DDIs have not been reported to influence the blood-pressure-reducing ability of losartan.

Valsartan is primarily eliminated by biliary excretion in feces (83% of the dose) with a small portion in the urine (13%) [255]. Unchanged drug in the excreta accounted for 81% of the dose with about 20% of dose recovered as metabolites including 4-hydroxyvaleryl metabolite (9%). *In vitro* studies show that CYP2C9 is the only form responsible for 4-hydroxylation of valsartan [256]. Valsartan is significantly taken up into OATP1B1 and OATP1B3 expressing HEK293 cells. Saturable ATP-dependent transport into membrane vesicles expressing human MRP2 has been observed. Taken together, these results suggest that OATP1B1 and OATP1B3 as the uptake transporters and MRP2 as the efflux transporter are responsible for the efficient hepatobiliary transport of valsartan [257]. No clinically meaningful pharmacokinetic drug interactions are observed when valsartan is coadministered with simvastatin, amlodipine, atenolol, digoxin, furosemide, glyburide, hydrochlorothiazide, indomethacin, and warfarin [249,258].

Similar to valsartan, telmisartan is minimally metabolized by CYP; a small amount of acyl glucuronide is found in circulation. Most of the administered dose is eliminated unchanged in feces via biliary excretion (>97%) [259]. Telmisartan has been shown to be an OATP1B3 substrate *in vitro* [61], and MDR1, MRP2, and BCRP are involved in the hepatic export of telmisartan acyl glucuronide [61]. A recent study shows that telmisartan is a potent inhibitor of PGP with an IC₅₀ of 0.38 μ M and a less potent BCRP and MRP2 inhibitor (IC₅₀: 16.9 and 25.4 μ M, respectively). MRP2 genetic polymorphisms appear to strongly influence interindividual variation in telmisartan pharmacokinetics in Japanese renal transplant recipients [260]. Telmisartan causes variable increases in serum digoxin levels [261], it is therefore recommended that digoxin levels need to be monitored in patients taking this drug combination. There are no clinically significant DDIs of telmisartan with warfarin, acetaminophen, amlodipine, glibenclamide, ibuprofen, and hydrochlorothiazide [249].

21.15 THE FUTURE OF CARDIOVASCULAR DRUG METABOLISM

The enzymology of CYP and transporters is reasonably well understood and methodology for prediction of DDI is sufficiently mature so that there should be fewer, if any, postmarketing drug withdrawals due to single-point DDI-mediated adverse events, such as mibefradil and cerivastatin. The understanding of genetic variation on drug disposition has made considerable contributions to cardiovascular drug safety and knowledge will continue to grow. Although the influence of biomarkers on drug safety and efficacy has not been as dramatic as promised, it is likely that improvements in sensitivity, selectivity, quantitation, and lower cost will bring modest success. Given the successes of physiologically based pharmacokinetic (PBPK) and pharmacokinetic-pharmacodynamic (PKPD) modeling, it is likely the next big thing will be integration of multiple parameters into models resulting in better predictivity of efficacy and DDI. In particular, the ability to quantitatively combine several pathways for drug disposition, such as vectorial uptake, efflux, and metabolism by multiple active systems, and incorporating genetic population variation should be possible in the coming years. Similarly, recent years have shown steady improvement in development of drugs with larger safety margins and more directed actions, as seen with antiplatelet drugs and antithrombotics.

22.1 INTRODUCTION

The past decade has witnessed a major shift in the relative distribution of therapeutic agents being considered to treat human illness. This change in therapeutic landscape has been the result of an overall decrease in the number of traditional or small-molecule drugs being approved, with a concomitant increase in the approval of novel therapeutic biologics or large-molecule drugs. This marked growth of biopharmaceuticals is a reflection of the maturation of biotechnology, both in terms of discovery and development of large-molecule drugs as well as the ability to consistently manufacture these complex molecules. However, despite an impressive evolution of the science, a sound understanding of the factors that control the systemic disposition and pharmacokinetics (PK) of these molecules remains to be defined.

In general terms, a biopharmaceutical is a protein- or nucleic-acid-based pharmaceutical substance used for therapeutic purposes, which is produced by means other than direct extraction from a native (nonengineered) biological source. An example of the latter is seen with insulin, which was extracted from pancreatic tissue of slaughterhouse animals [1]. A high level definition of biopharmaceuticals may be regarded as

molecules that are produced using recombinant DNA technology in expression cells that are amplified in bacterial or mammalian cell culture.

In addition to the dramatic differences in manufacturing processes between biopharmaceutical drugs and traditional drugs, molecular size is another obvious distinction: the molecules of a biological medicine are much larger, have far more complex spatial structures and are much more diverse, or heterogeneous, than the small molecules that make up traditional drugs. A molecule of a biological medicine is typically a protein made of a chain of 20 to several hundred amino acids within a complex three-dimensional structure. Examples of biopharmaceuticals include monofunctional antibodies that bind one antigen or target, bifunctional antibodies that bind two targets, antibody fragments, peptides, fusion proteins, plasma-derived proteins, and various soluble receptors or receptor ligands.

A second marked difference between biopharmaceuticals and small molecules is observed in the routes of administration. The route of administration of a biopharmaceutical is very different from a traditional drug taken as a pill or capsule, and each drug is developed with a unique route of administration. Typically, biopharmaceuticals are given intravenously, subcutaneously, or intramuscularly, as they generally cannot be orally administered due to degradation in the gastrointestinal (GI) tract. However, the oral delivery of biopharmaceuticals is an active area of research [2]. In addition, many biopharmaceuticals are administered in a clinical setting, although recently for some chronic indications (e.g., rheumatoid arthritis), molecules exist that are self-administered subcutaneously with autoinjector devices.

Another aspect in which biopharmaceuticals are very different from small-molecule drugs is observed with the routes of elimination and observed PK. The elimination pathways for small-molecule drugs are governed by hepatic metabolism (e.g., cytochromes P450) and the subsequent half-lives are in the range of minutes or hours [3]. In contrast, the half-lives of biopharmaceuticals, antibody drugs, for example, are in the order of weeks [4]. For small-molecule drugs, many safety problems occur around the time of $C_{\max}$; however, for biopharmaceuticals, the focus is typically around total drug exposure or area under the curve (AUC) instead of $C_{\max}$.

Biopharmaceuticals present several advantages over small organic molecule therapeutics in treating many diseases. Foremost, the selectivity of biologics is unsurpassed, and because of this inherent specificity in biological function, protein therapeutics present minimal disturbances to normal biological functions, which limits the potential for untoward side effects. Biopharmaceuticals can be grossly separated into different categories: peptides, proteins (enzymes), and antibodies. For the purpose of this chapter, peptides and proteins have been combined based on similar clearance mechanisms and strategies used to enhance their PK properties as therapeutic agents. Antibodies are described in a separate category. The overall focus of this chapter is to highlight the factors that govern the disposition and PK of the aforementioned biopharmaceuticals.

Peptide or protein biopharmaceutical agents are often designed to replace a deficient or abnormal protein pathway in patients or introduce a novel biological function in order to circumvent a particular physiological deficiency. Peptides of various size and derivation are used as drugs across a wide range of therapeutic regimens and represent one of the fastest growing classes of new drugs in the arena of drug discovery. Within the literature, the distinction between peptide and protein therapeutics can be somewhat inconsistent; thus, by definition, any polymer consisting of two or more amino acids linked by amide bonds is termed a *peptide*.

The increasing importance of peptide therapeutics in drug discovery today can be attributed to two primary factors. First, the evolution of drug discovery techniques, such as phage display and combinatorial chemistry, has led to the identification of numerous peptide drug candidates that may provide hope as biopharmaceutical agents [5,6]. Second, advances in genetic engineering and chemical synthesis have enabled the large-scale production of peptides that previously were only available in small quantities [7]. Despite the technological advances detailed above, however, when compared with antibodies and proteins, the disposition of peptide drug candidates is plagued with a critical drawback; namely, they are rapidly eliminated from the systemic circulation.

Oral absorption of peptide and protein therapeutics is prohibited by numerous properties associated with the GI tract, including the acidic environment of the stomach (pH 1–3), which is destabilizing to most peptides and proteins, and the production of large amounts of proteolytic enzymes that are secreted into the digestive tract (discussed in detail below). This barrier to the oral delivery of peptides and proteins has required the pursuit of alternate, more invasive routes of administration, including intravenous and subcutaneous dosing. The frequency of using these alternate routes can be minimized with biologic therapeutics that have sufficiently prolonged half-lives (>25 days), which should promote less frequent dosing. However, peptides and proteins are typically cleared from the bloodstream within minutes to hours after administration, and as a result in many cases, there is insufficient drug exposure in the target tissue to elicit a pharmacological effect. The short plasma half-lives observed for peptides typically result from rapid renal clearance due to the small size of the peptides (<60 kDa for the kidney filtration cutoff threshold) and/or from enzymatic digestion in the blood, kidneys, or liver [8,9]. To remedy this issue, a number of strategies have been developed to reduce renal excretion. Consequently, strategies employed to increase the half-life typically require mechanisms to reduce amide hydrolysis or degradation in order to maintain biological activity of the chimeric peptide or protein once serum residence times have been extended.

22.2 RENAL CLEARANCE OF PEPTIDES AND PROTEINS

As described above, one of the major problems for therapeutic peptides is that these drug candidates are rapidly cleared from the circulation via the kidneys [10]. To address the issue of rapid renal elimination, numerous technologies have been developed to increase the *in vivo* plasma residence time of peptide drugs and these will be discussed in more detail in the subsequent sections of this chapter. Overall, these approaches are all designed to make the peptide larger (generally >60 kDa) to retard excretion through the kidneys.

22.3 ENZYMATIC CLEARANCE MECHANISMS OF PEPTIDES AND PROTEINS

Despite the fact that the molecular weight for most peptides is typically below 10 kDa and therefore they should be readily filtered by the glomerulus in the kidney, rapid elimination of peptides due to renal clearance cannot completely account for the exposure

Figure 22.1 Chemical interactions and reactions of the peptide backbone.

issues observed for some peptides, as for example, some half-lives exceed the glomerular filtration rate (GFR) of about 100 mL/min for a normal 70 kg man [11]. To this end, the short half-lives of many small peptides (<10 min) cannot be completely explained by renal clearance and is most likely due to rapid enzymatic degradation.

The process of this metabolic degradation is also called *proteolysis* and is best described in terms of chemical hydrolysis (Fig. 22.1). For peptides, blood, liver, and kidney are probably the most important sites of metabolism, as they contain a wide variety of peptidases [9]. However, because of the physical–chemical properties (e.g., hydrophilicity) of many peptide drugs, proteolytic enzymes in the blood may play a more important role in their metabolism [12].

The mechanism for peptide hydrolysis, like all enzyme-mediated catalytic reactions, requires interactions with appropriate active site groups (Fig. 22.2). For the hydrolysis reaction to occur, the combined action of the active site catalytic groups is essential [13,14], as the peptide bond represents a strong linkage that has a high degree of double-bond character (a consequence of the degree of delocalization of the nitrogen lone pair into the carbonyl group). The strength of the peptide bond weakens in the first step, when a nucleophile, such as water or a serine OH group, attacks the carbonyl carbon atom, which results in a tetrahedral intermediate bearing an oxyanion. In this sequence, the nucleophilic attack is aided by a general base that accepts the proton from the nucleophilic OH group (Fig. 22.2a). The intermediate is stabilized by electrophilic catalysis, which is provided by hydrogen bonds from the oxyanion-binding site to the carbonyl oxygen. This is followed by the expulsion of the leaving group, in this case the amine, from the tetrahedral intermediate. Because the amine is a poor leaving group, it must be protonated by a general acid to be able to depart (Fig. 22.2b). In short, similar to chemical hydrolysis reactions, proteolysis of the peptide bond cleavage proceeds via the formation and decomposition of the tetrahedral intermediate, which is facilitated by general acid–general base catalysis, mediated by a single proton carrier, often an active site histidine side chain in many cases [15].

22.3.1 Mechanism of Peptide Hydrolysis

In general terms, there are four distinct peptidase mechanisms, which are loosely linked to the primary means of the hydrolysis reaction (e.g., serine, cysteine, aspartic, and metallopeptidases). The most obvious difference between the enzyme mechanisms is the presence or absence of a covalent acyl-enzyme intermediate in the reaction pathway [16–18]. The catalyses of serine and cysteine peptidases involve the covalent intermediate (ester and thiolester, respectively) (Fig. 22.2a), while the aspartic and the metallopeptidase catalyses do not (Fig. 22.2b). For hydrolysis reactions carried out by

Serine protease

Cysteine protease

the latter two groups, the substrate is attacked directly by a water molecule rather than by a serine or cysteine residue.

Interestingly, despite the mechanistic differences, the basic catalytic features of the enzymes described above is quite similar. Hydrolysis of the peptide bond is an addition–elimination reaction involving a tetrahedral intermediate. For these reactions, metal ions and functional organic groups promote hydrolytic cleavage peptides through (i) electrostatic activation of the substrate in the ground state or stabilization of the transition state by metal ion coordination, hydrogen bonding, or proton transfer; (ii) stabilization of leaving group by metal coordination, hydrogen bonding, or proton transfer; (iii) nucleophilic attack on the substrate by functional group or by metal-coordinated hydroxide, which is generated at neutral pH by Lewis-acid activation of metal-coordinated water; and (iv) generation of the nucleophile via proton abstraction by a basic group.

22.3.2 Peptidase Selectivity

Peptide-metabolizing enzymes can be separated into two major classes (Fig. 22.3): the endopeptidases, which break peptide bonds within the molecule of peptides, and the exopeptidases, which catalyze the removal of one or two amino acids from the N-terminus or the C-terminus of a peptide [9]. Exopeptidases that remove dipeptides from the N-terminus of peptides are called *dipeptidyl peptidases*, while those that remove dipeptides from the C-terminus are termed *peptidyl dipeptidases* [19]. In terms of substrate recognition, each peptidase appears to have its own cleavage specificity of peptides. In some cases, multiple enzymes may hydrolyze a particular peptide to

Figure 22.3 An illustration of the two types of peptidases and their general activity.

Figure 22.4 Peptidase activity on bradykinin.

yield several products. For example, during a single passage through the pulmonary vascular bed of the lung, no fewer than five of the eight peptide bonds of bradykinin are hydrolyzed (Fig. 22.4) by a variety of peptidases [20]. In contrast, glucagon-like peptide 1 (GLP-1) is specifically hydrolyzed by removal of His-Ala dipeptide of the N-terminus by dipeptidyl peptidase IV (DPPIV) [21]. In this fashion, the information of cleavage specificity of a given peptide drug is important, because knowing the cleavage site allows a rational modification of the peptide drug in order to improve its metabolic stability.

22.4 REDUCING PEPTIDE AND PROTEIN CATABOLISM

22.4.1 Blocking Proteolysis of Peptides and Proteins to Increase Plasma Half-Life

The attachment of polyethyleneglycol (PEG) to a drug molecule, termed *PEGylation*, was first pioneered by Davis and colleagues in the 1970s [7]. The primary objective of this chemical modification was to modify the PK profile of a peptide drug by extending the half-life of the molecule on systemic administration. PEGs are amphiphilic and relatively chemically inert polymers consisting of repetitive units of ethylene oxide [8]. PEGs are named based on the number of ethylene oxide units in the polymer chain; a large variety of PEG molecules with different molecular weights are commercially available. PEGs can be presented with various configurations categorized in two main

Figure 22.5 Types of pegylation for protein modification.

classes of linear or branched polymers (Fig. 22.5). Moreover, PEGs can be further divided into two groups: PEGs with free hydroxyl groups at both ends and PEGs with one or two methoxylated end group(s) [9]. Multiple low molecular weight PEG molecules (5 kDa), or single high molecular weight PEG molecules (40 kDa) can often be attached at the N-terminus or C-terminus of a peptide without affecting biological activity [10].

The attachment of PEG to peptides is a widely accepted method to increase serum residence times [11]. For example, PHA-794428 is a PEGylated version of somatropin (human growth hormone). The PK of PHA-794428 somatropin is mediated by two mechanisms. The primary mechanism is via clearance by glomerular filtration [12]. When the PK of both molecules (PHA-794428 and somatropin) were evaluated in humans following single subcutaneous administration it was observed that the PEGylation of somatropin with a 40 kDa PEG resulted in a 10- to 20-fold increase in AUC with a similar increase in half-life when compared with somatropin [13].

Site-specific PEGylation has also been achieved in combination with the application of protein chemistry. For example, GLP-1-(7-36) is an endogenous hormone with potential as an antidiabetic agent but due to its extremely short half-life has limited therapeutic potential as the native peptide. Through PEGylation of lysine 34, the residue directly adjacent to the DPPIV peptidase cleavage site, the stability of GLP-1 in the presence of DPPIV is increased >50-fold [22]. The *in vivo* half-life is extended as well but remains short (<1 h) likely due to the renal clearance component of the small PEGylated peptide. Site-specific PEGylation also demonstrated the ability to significantly increase the half-life of IL-15 from minutes to days [23]. In addition, the authors suggest that the strategic placement of the PEG can be useful in the modulation of protein-protein interactions. Several strategies have been developed to introduce PEG molecules specifically into proteins.

The introduction of PEG can also reduce the potential for immunogenicity of some proteins or specific protein sequences. Although site-specific conjugation strategies have been developed, which improve the yield and specificity of the conjugation site, issues remain with the cost and intrinsic heterogeneity of the PEG itself. PEGylated

proteins can also give rise to toxicity. Specifically, renal tubular vacuolation has been observed in animal models. Renally cleared PEGylated proteins or their metabolites may accumulate in the kidney, causing formation of PEG hydrates that interfere with normal glomerular filtration.

The replacement of an L-amino acid by a D-amino acid of a peptide to reduce its susceptibility to enzymatic cleavage is a common strategy to prolong intrinsic plasma half-life of the peptide [24]. For example, natural gonadotropin-releasing hormone (GnRH) has a very short half-life in plasma, which limits its clinical usefulness [25]. However, when a glycine was substituted with a D-tryptophan at position 6 of the natural GnRH, the resulting molecule, triptorelin, has a half-life about 10-fold longer (2 h) than that of natural GnRH, which affords a role for the treatment of central precocious puberty in pediatrics [26]. However, the strategy of substitution of L-amino acids with D-amino acids does not always work and care must be taken to introduce the amino acid substitution in a position where proteolysis occurs [27].

A second example where unnatural amino acid linkages have been employed is observed with β -amino acid peptides [28]. In peptides that comprise α -amino acids, the carboxylic acid group and the amino group are bonded to the same carbon center (also known as the α -carbon because it is one atom away from the carboxylate group). In contrast, β -amino acids have the amino group bonded to the β -carbon (Fig. 22.6). The strategy for this modification is that substitution of an α -amino acid located at the hydrolytically liable peptide cleavage site with a β -amino acid would introduce an extra carbon in the peptide backbone and thus confer resistance to proteolytic cleavage (Fig. 22.7) without necessarily abolishing enzyme binding [29].

Figure 22.6 Illustration of the natural (L) amino acid compared to non natural (D) amino acid.

Figure 22.7 Illustration of the natural (L) amino acid compared to non natural (D) amino acid.

As mentioned above, a separate approach to enhance peptide stability is to modify either or both the C-terminus and N-terminus of peptides to minimize their susceptibility to exopeptidases. For instance, N-pyroglutamylation of GLP-1 led to an improved enzymatic stability of and a subsequent increase in *in vivo* glucose-lowering effect in adult obese diabetic (ob/ob) mice [30].

The conjugation of high polymeric mass to peptide drugs has previously been described to decrease the fraction of renal clearance of a peptide and also represents another way to improve their metabolic stability [22,30]. In this fashion, the conjugation of a peptide with PEG increases its hydrodynamic radius and improves its stability toward peptidases. For example a dual-acting peptide's (DAPD) pharmacological effects are attenuated because of its poor metabolic stability. In an effort to overcome a short plasma half-life of the hybrid peptide, DAPD was PEGylated at the C-terminus to enhance its metabolic stability and prolong the duration of pharmacological action [31].

Alternate methods to develop proteolytic resistant peptides have been demonstrated through the cyclization of peptides with olefin metathesis. Specifically, ring-closing metathesis (RCM) links *N*-amino acid to *N* + 4-amino acid by forming a carbon-carbon bond [32]. The end result is the generation of peptides with increased helical structure and proteolysis resistant peptides that are more suitable as therapeutic candidates due to their increased stability. For example, Fuzeon or enfuvirtide is a 36-amino-acid peptide that confers resistance to HIV-1 infection but remains a last option due to short lived efficacy because of rapid elimination [33]. Through engineering in two ring-closing or stapled sites, the PK of the ring-closed peptide (RCP) showed an ~200-fold increase in half-life from 11 min for the parental peptide to 2040 min [34]. Numerous additional RCP have demonstrated similar increases in stability and proteolysis resistant behavior [35–37]. Alternatively, strategic replacement of amino acids that trigger proteolytic degradation can be selectively replaced with more stable amino acids [38]. Yet another strategy is to replace labile amino acids with the introduction of nonnatural amino acids, which has also demonstrated the ability to increase *in vivo* half-life of peptide and protein fragments.

The primary disadvantage of techniques that focus solely on controlling proteolysis, where a reduction in catabolism can be demonstrated in most of the examples, the principal elimination pathway for the peptide/protein still results in significant renal clearance of the modified peptide/proteins. Future efforts will have to combine proteolytic stabilizing techniques with specific strategies to reduce renal clearance.

22.5 HALF-LIFE EXTENSION OF PEPTIDES AND PROTEINS FUSED TO SERUM PROTEINS

In addition to PEGylation, other approaches toward improving the PK of peptides that are based on binding to or fusion with long-circulating serum proteins such as albumin have been developed. Albumin is the most abundant protein in the blood plasma and is produced in the liver as a monomeric protein of 67 kDa. In addition to its role in regulating the osmotic pressure of plasma, albumin also functions as a transporter of endogenous small molecules such as long-chain fatty acids, bilirubin, and steroid hormones [14]. Albumin also binds with high affinity to a broad range of drugs influencing their PK properties [15].

22.5.1 Attachment to Carrier Proteins

Albumin has a simple molecular structure and is highly stable. It is abundantly present in vascular and extravascular compartments with a circulation half-life of 19 days in humans [16]. Recent studies have shown that this long serum half-life is due to a recycling process mediated by the neonatal Fc receptor (FcRn), similar to that observed for IgG molecules [17]. Some companies have taken advantage of these properties and have fused human serum albumin (HSA) with hormones to serve as a macromolecular carrier for drug delivery [18].

22.5.2 Attachment to Antibody Fragments

A second approach pioneered by Amgen is the attachment of Fc regions to peptides to improve PK. One example is romiplostim, an Fc-fusion protein analog of thrombopoietin, a hormone that regulates platelet production [19]. In this instance, the company made use of the natural antibody constant region half-life extension mechanism, provided by FcRn recycling of antibodies, and any other peptide or protein fused to an antibody Fc domain [20].

22.6 HALF-LIFE EXTENSION OF PEPTIDES AND PROTEINS THROUGH POSTTRANSLATIONAL MODIFICATION

22.6.1 N-Terminal Acetylation

The N-terminus of proteins contains a methionine residue capable of undergoing multiple modifications. With the exposed N-terminus, methionine can be acetylated, triggering methionine-aminopeptidase activity, which cleaves off the acetylated methionine residue. The fate of the newly exposed residue is determined partially by size; specifically, if the amino acid residue is small enough, it too will be acetylated. The acetylations can trigger the ubiquitin degradation system.

22.6.2 Phosphorylation

Phosphorylation of serine or threonine residues has demonstrated the ability to increase clearance of endogenous proteins. For example, the phosphorylation of huntingtin at Ser13 and/or Ser16 leads to accelerated clearance of huntingtin. The phosphorylation also triggers additional modifications, including ubiquitination and acetylation, which has been discussed in further detail later in this chapter. Alternatively, a reduction in autophagy has been observed for Ataxin-7 on posttranslational modification of lysine 257. Blocking anticipated phosphorylation sites may lead to unique biodisposition of protein therapeutics.

22.6.3 Engineered Glycosylation

Protein glycosylation sites also contribute to the diverse biological properties of proteins [39]. Specific changes in glycosylation patterns influence all facets of protein behavior, including expression, proper folding, tertiary stability, biodistribution, activity, and

ultimately the half-life of a protein [40–43]. The ability to affect half-life through changes in the glycosylation state of proteins has been recognized and a significant effort has been made to harness the power of glycosylation in the development of therapeutic proteins [44–46]. The two most common forms of glycosylation are N-linked and O-linked. The general motif for N-linked glycosylation of proteins is Asn-X-Thr/Ser, where X can be any amino acid residue except proline [47]. *N*-Glycans share a common pentasaccharide core and are designated by subcategory as high mannose type, complex type, or hybrid type. In contrast, O-glycosylation does not appear to have a formal consensus sequence and O-linked sugars are commonly attached to serine or threonine residues through an *N*-acetylgalactosamine (GalNAc). Two additional types of glycosylation, *C*-mannosylation and glycosylphosphatidylinositol are not discussed further due to limited scope in therapeutic protein design at this time. In addition to the primary sequence motif that indicates potential for glycosylation, it has been proposed that glycosylation sites commonly occur at regions of alternating secondary structure [48]. The increased ability to predict glycosylation sites from primary structure combined with other rule-based computational approaches should aid in the design of novel sites for glycan introduction into proteins in order to enhance the PK properties of protein therapeutics [47].

A number of methods have been employed to alter glycosylation of recombinant proteins. Foremost, the choice of cell line can influence the type and extent of glycosylation, which can further be manipulated by altering expression conditions and media content. Selective pressure of CHO cell lines has been used to isolate mutants in the glycosyltransferase genes [49,50]. Other cell lines are also capable of manufacturing glycoproteins, including human embryonic kidney (HEK) cells, baby hamster kidney (BHK) cells, mouse myeloma cells such as NS0, and the human retinal cell line PERC.6.

In addition to the modification of glycan patterns through strategic choice of expression system, new glycan sites can also be introduced in order to try to improve protein stability, formulation conditions, and PK properties. Site-directed mutagenesis to engineer the glycosylating motif into the therapeutic protein can be attempted [44]. However, this strategy is not trivial and often numerous attempts have to be made in order to introduce novel sites for glycan structures; however, the population of these novel sites to a high degree of fidelity remains quite variable [51]. The variable success of this approach may be indicative of additional factors that contribute to the potential for different protein glycoforms, including microconformations adopted by the protein during biosynthesis and protein folding process. To circumvent these uncertainties, a site-directed mutational approach in combination with specific labeling chemistry has been employed to introduce stoichiometric amounts of glycosylated protein to yield highly homogenous protein preparations [52].

Introducing novel glycan sites may also lead to changes in receptor binding and therefore *in vivo* activity. For example, the specific activity of wild-type DPPIV is significantly higher than that of Gln3191-DPPIV. Alternatively, Gln83 and Gln686 only displayed modest changes in activity compare to wild-type (fully glycosylated enzyme) indicating specific regions of protein glycan structure may have greater impact on function than others [53]. To minimize reduction in activity as a result of introducing novel glycosylation sites internal to the protein, use of the termini of the protein sequence for the introduction of a glycan motif is another strategy that appears more predictive and reproducible [44].

The impact of N-linked glycosylation in native and engineered proteins is readily apparent on review of physical and PK properties of different proteins [54,55]. Another example is follicle-stimulating hormone (FSH), which is a highly glycosylated protein that offers medical advances as a treatment for infertility. The hormone contains two subunits: α and β . Each subunit has two potential sites for glycosylation and structural characterization demonstrated glycol forms with increased sialic acid content tended to possess longer circulation half-lives. Through N-terminal extension of the protein sequence to introduce two novel glycan sites, a modified FSH coined FSH1208 displayed prolonged half-life and efficacy *in vivo* [44]. Lastly, L-asparaginase derived from *Escherichia coli* was chemically modified with *N*-acetylneuraminyl lactose [56]. The thermal stability as well as proteolytic stability was improved for this modified protein. In addition, mouse PK studies were performed with the two materials, which illustrated that the modified protein has a twofold increase in half-life.

22.6.4 Amino Acid Extension Techniques

A polypeptide tethering technique was explored largely based on the premise of the advantages of PEGylation. This strategy focuses on the design of a soluble, chemically stable, and predominantly unstructured polypeptide that provides a maximal hydrodynamic radius to enhance protein PK. The intrinsic physiochemical properties of individual amino acids were carefully explored in designing the proper polypeptide chain; hydrophobic amino acids (e.g., F, I, L, M, V, W, and Y) that typically contribute to compact structures and/or protein aggregation were avoided. Hydrophobic amino acids also play a critical role during binding of peptides to major histocompatibility complex (MHC) class II-driven immune responses. Other amino acids have properties that are undesirable in a molecule intended for clinical usage. For instance, amide-containing side chains such as N, Q, and W are subject to chemical instability during long-term storage of protein drugs, and positively charged side chains such as H, K, and R can facilitate binding to cell membranes. Cysteine residues can cause heterogeneous disulfide cross-linking.

22.7 ANTIBODIES AS THERAPEUTIC PROTEINS

Antibodies, or immunoglobulins, are generated during a humoral immune response critical for the protection of higher organisms. These macromolecules are grouped into five subclasses or isotypes based on the structure of their heavy chains and consist of IgA, IgD, IgE, IgG, and IgM. IgG represents the most important class of antibodies as it is the most abundant in serum at ~ 12 mg/mL. The IgG isotype is further divided into four subclasses, IgG1, 2, 3, and 4, with each subclass playing particular roles during an immune response [57]. In general, IgG antibodies have half-lives in human of ~ 21 days with the exception of IgG3, which has a 7-day half-life [58], which has been shown to be due to a single amino acid in the Fc region (H435R) which results in less efficient FcRn-dependent recycling (see below [59]).

22.7.1 General Antibody Structure

Each antibody contains two identical heavy and light chains made up of variable and constant regions. Each chain contains an N-terminal antigen-binding variable domain,

or Fab, and a C-terminal constant domain, or Fc. The antigen-binding site is contained within the Fab fragment and is formed by the combination of the heavy and light chain variable region domains, in particular, through three complementary determining regions (CDRs) in each of the heavy and light chain, which define the specificity and affinity of a given antibody for its antigen or target. The light chain constant region has one domain, CL, whereas the heavy chain constant region has three domains, CH1, CH2, and CH3, and a hinge region. Interchain disulfide bonds between CL and CH1 stabilize the association of the heavy and light chain, and multiple interchain disulfide bonds reside in the hinge region between CH1 and CH2 and function to stabilize the heavy chains, while the hinge allows for flexibility of the Fab region relative to the Fc [57,60]. The heavy chain constant domains or Fc region of an immunoglobulin molecule, in particular CH2 and CH3, are important for imparting function onto the molecule; they interact with Fc receptors (FcRs) on numerous effector cells, including macrophages, monocytes, and natural killer cells to potentiate effector functions either through antibody-dependent cellular cytotoxicity (ADCC) or antibody-dependent cellular phagocytosis (ADCP), or with complement proteins to initiate complement-dependent cytotoxicity (CDC) [61,62]. These heavy chain domains also interact with the FcRn (described below) to regulate the functional lifespan of IgG molecules. The general structure of an IgG is shown in Fig. 22.8.

Figure 22.8 General antibody structure. Fc, crystallizable fragment; Fab, antigen-binding fragment; ABS, antigen-binding site; CDR, complementarity-determining regions; Light chain, VL and CL; Heavy Chain, VH, CH1, CH2, and CH3. The carbohydrate-binding region is located in CH₂ of Fc.

Monoclonal antibodies (mAbs) have become an important therapeutic option for many diseases, including cancer, inflammatory, and infectious diseases (reviewed in Refs 63 and 64). Antibody development platforms include but are not limited to murine hybridomas, chimeric mAbs with human Fc domains, humanized antibodies to remove the mouse/rodent components through molecular biology techniques to reduce immunogenicity, and fully human mAbs derived from phage libraries or transgenic mice that express human IgG loci to generate mAbs [65]. In general, IgG antibody half-life increases with increasing amount of humanization, ranging from mouse to chimeric to humanized to fully human [58,66,67].

22.7.2 Antibody Recycling Through the Neonatal Fc Receptor (FcRn)

FcRn is a heterodimer of the MHC class I such as H-chain and the β -2 microglobulin L-chain [68,69]. The presence of FcRn was first proposed by Brambell *et al.* [70,71], who predicted the presence of a saturable receptor that played a role in pre- and postnatal epithelial transcytosis of IgG across the placenta in humans or intestinal epithelium in rodents, respectively, and in the protection of IgG from catabolism leading to long serum half-life. An additional role for FcRn in immunoglobulin homeostasis was further confirmed in β -2 microglobulin KO [72–74] and FcRn KO mice [75], where IgG isotype Abs were rapidly cleared, as they were present at 10- to 15-fold less concentration than normal and thus lack protection, whereas other isotypes such as IgM and IgA had no change in serum concentration.

The vascular endothelium is the main site where FcRn is expressed [75], but it is also expressed on intestinal, kidney, and bronchial epithelial cells [76] as well as hepatocytes and phagocytic cells of the reticuloendothelial system (RES) and plays a role in clearance and recycling [66].

More recent studies have confirmed a role in immunoglobulin homeostasis by regulating the turnover of IgG [75,77]. Interaction of IgG isotypes with FcRn, particularly IgG1, 2, and 4, occurs after pinocytosis of immunoglobulin molecules from the bloodstream into intracellular endosomes, where, in a pH-dependent manner, antibodies now bind to FcRn and are protected from degradation; those that fail to bind FcRn are catabolized in the lysosomes. On recycling to the cell surface, the IgG molecule is released in the pH 7.4 environment of the bloodstream, thus extending the half-life of the molecule. The proportion of IgG processed through the recycling versus destructive pathway is believed to be important in determining the persistence of IgG in the circulation [78].

There is growing evidence that increasing affinity for FcRn can positively influence the half-life of IgG molecules. By altering Fc-region amino acids that interact with FcRn to increase the endosomal binding at pH 6 and promote recycling, while maintaining release into the bloodstream at pH 7.4, it is this differential pH-dependent binding that has been targeted through Fc engineering approaches to generate mAbs with extended half-lives [62,79]. Extending therapeutic antibody half-life would be advantageous to allow for reduced dosing frequency, decreased dosing amount, increased bioavailability, and improved patient compliance. Much effort has been expended to map the FcRn-binding sites within the IgG constant regions, and the majority of the amino acid residues described as affecting binding have been found to lie within the CH2–CH3 interface of the constant region [59,80] as this region interacts directly with FcRn. The pH dependency of binding is due minimally to conserved histidine residues at positions H310 and H435, which are protonated at acidic and neutral pH or deprotonated at physiological ($\sim$ 7.2–7.4) pH [81,82].

To date several groups have generated Fc region mutants that demonstrate increased half-life in preclinical animal species, including mice and nonhuman primates. Dall'Acqua and colleagues have described the "YTE" mutant after phage display mutagenesis of Fc yielded several sequence variants that improved *in vitro* binding to mouse FcRn at acidic pH and also at pH 7.4 [83]. The residues of interest for the YTE site-directed mutational variant mapped to the CH2 domain, specifically to residues M252(Y), S254(T), and T256(E). PK studies in mice demonstrated those variants that bound more tightly to mouse FcRn at both pH 6 and 7.4, including the YTE variant, and PK profiles with lower exposures and reduced half-lives compared to the parental antibody. The YTE mutations were engineered into the anti-respiratory syncytial virus (RSV) mAb MEDI-524 and yielded improved human FcRn *in vitro* binding at pH 6 but not at pH 7.4. The resulting PK profile of this variant in cynomolgus monkeys demonstrated a fourfold improvement in half-life compared to the parental molecule [84]. This variant, MEDI-557, is currently in phase I clinical trials where validation of improved half-life could be demonstrated.

Using molecular modeling to identify Fc residues that might interact with FcRn, Hinton *et al.* [85,86] demonstrated extended mAb PK profiles by incorporating T250Q/M428L mutations into an IgG2 and IgG1 anti-hepatitis B virus mAb and showed a 2- to 2.5-fold improved half-life in rhesus monkeys, respectively. These variants demonstrated an $\sim 28\times$ and $37\times$ higher affinity for rhesus FcRn binding by surface plasmon resonance at pH 6 versus the parental mAb and showed no binding at pH 7.4 and above for the IgG2 and IgG1 variants. Assuringly, there was little to no negative effect on ADCC or CDC activity, or loss of protein A binding (i.e., a matrix used for purification of monoclonal antibodies) by the variant antibodies, which suggests that the CH2–CH3 interface important for all these interactions is not affected by the incorporation of the mutations.

In the first of several reports to look at the importance of altering Fc region residue N434, Petkova *et al.* [87] generated variants N434A and T307A/E380A/N434A that demonstrated enhanced pH-dependent binding to human FcRn *in vitro* and a correlative half-life improvement *in vivo* versus the parental antibody in mice transgenic for the expression of human FcRn. However, these variants showed no improved half-life in wild-type mice, a result that demonstrates the importance of screening modified Fc variants in the correct molecular context [88].

A second analysis of position N434A by Yeung *et al.* [89] revealed an increased binding to human and primate FcRn at pH 6.0 but negligible binding at pH 7.4 by this variant, which led to an increased exposure and half-life with decreased clearance compared to the wild-type parental mAb. Interestingly, variant N434W, which had 80-fold improved binding to human and primate FcRn at pH 6 as well as increased binding at pH 7.4 revealed a PK profile similar to the wild-type mAb, which demonstrates the importance of preserving the efficient release of IgG at pH 7.4 from FcRn into the bloodstream [89]. This is the first group to demonstrate a potential ceiling for the amount of improvement in differential binding to FcRn in a nonhuman primate system.

Finally, Deng *et al.* demonstrated differential PK with an anti-tumor necrosis factor (TNF) variant mAb with changes in the Fc region of N434A and N434H [90]. The N434A variant mAb had similar *in vitro* binding properties to FcRn as the parental mAb and thus in mice had a similar PK profile, whereas N434H had increased pH 7.4 FcRn binding *in vitro* and demonstrated a more rapid clearance and lower bioavailability versus the parental mAb *in vivo*. Furthermore, both variants demonstrated higher affinity

in vitro binding at pH 6 compared to the parental mAb and demonstrated improved PK characteristics in cynomolgus monkeys, including higher exposures *in vivo*, again confirming the importance of tuning the differential binding effect to promote improved pH 6 binding, while maintaining low binding affinity to promote efficient release at pH 7.4.

In addition to improved PK profiles through FcRn modifications, recent examples of improved pharmacodynamics due to improved FcRn binding have also been reported. Zalevsky *et al.* [91] demonstrated three- to fivefold improved half-lives with the anti-vascular endothelial growth factor (VEGF) mAb bevacizumab and the anti-epidermal growth factor receptor (EGFR) mAb cetuximab with the LS series of mutations (M428L/N434S) in cynomolgus monkeys and huFcRn Tg mice, respectively, and both demonstrated an improved *in vivo* efficacy in xenograft tumor models, the first demonstration of improved pharmacology manifested as increased tumor-suppressing pharmacodynamics due to antibodies with longer half-lives.

Yeung *et al.* from Genentech also demonstrated an improvement of PK in cynomolgus monkeys of bevacizumab variants that contained modified Fc residues. Interestingly, the variant T307Q/N434A also demonstrated improved pharmacology in mouse colorectal tumor xenograft models despite having no improved pH-dependent murine FcRn binding or improved PK parameters in mouse [92]. With a finding similar to Deng *et al.* [90], Yeung *et al.* also demonstrated that a 10-fold improvement in pH 6 binding to FcRn may be the upper limit as a greater than 10× increase in binding affinity did not lead to improved PK or half-life but instead led to some degree of a reduced or deleterious effect on PK.

While it appears that there is a direct correlation between improved *in vitro* binding to FcRn at pH 6 and improved *in vivo* PK profiles from the examples presented so far, other Fc-region modification examples that improve FcRn binding *in vitro* have not shown such enhancement *in vivo*. For example, incorporation of the half-life improving T250Q/M428L mutations described by Hinton into an anti-TNF antibody demonstrated ~40-fold improved *in vitro* binding to cynomolgus FcRn but showed no improved PK in cynomolgus monkeys [93,94]. Likewise, Gurbaxani *et al.* have shown no correlation between mAb Fc:FcRn affinity and *in vivo* half-life improvement [95]. Thus, other factors in addition to Fc:FcRn affinity are involved in improvement of PK parameters, which could include absolute (vs relative) FcRn:IgG Fc affinity at both pH 6 and 7.4, the kinetics of the interactions, and the contribution of other clearance mechanisms, including target-mediated disposition, in addition to the FcRn-mediated clearance pathway [79,90]. Interestingly, in a recent report, Suzuki *et al.* [96] analyzed the ~25 FDA, EU, and Japanese approved therapeutic antibody and five Fc-fusion protein drugs and demonstrated differential FcRn binding due to affinity differences between Fc interactions with FcRn, which suggests that the overall CH2–CH3 Fc structure may contribute to the relatively rapid clearance of Fc-fusion proteins when compared to full antibodies. Ultimately, clinical validation of several of these modifications or of one modification in several applications will be needed to understand the global utility of this Fc-modified half-life extension approach.

22.7.3 Antibody Targeting and Influence on Pharmacokinetics

The characteristics of an antigen targeted by a monoclonal antibody may play a role in the disposition and elimination of the dosed antibody. In general, anticytokine or antisoluble protein antibodies do not seem to be markedly altered in clearance due to their interaction with their target as evidenced by dose proportional linear clearance.

Cell surface receptors on the other hand may have a significant impact on clearance particularly for mAbs that are cleared through internalization of an antibody–antigen complex [66,97,98]. For example, cetuximab, and trastuzumab, an anti-human epidermal growth factor receptor 2 (HEGFR2) mAb, both demonstrate nonlinear clearance [97,98]. The extent that a membrane-associated antigen affects mAb clearance depends on the density and distribution of the target antigen on the cell surface and the relative internalization efficiency and turnover rate of the receptor [66].

Other influences on mAb PK include the generation of antidrug antibodies that may act to neutralize the drug or increase its clearance, thus reducing its efficacy. The majority of the currently marketed therapeutic proteins and mAbs demonstrate some level of immunogenicity, although use of humanization technologies and fully human antibodies [63] or engineering efforts to remove immunogenic epitopes [99] has reduced the incidence compared to that observed for first-generation mouse mAbs or next-generation chimeric mAbs. Fully human mAbs theoretically are less immunogenic but still contain CDRs that are unique to each therapeutic protein. In general, the fully human proteins or mAbs have demonstrated lower or no degrees of immunogenicity.

22.8 SUMMARY

As the number of approved biologics increases over the coming years, numerous opportunities for the clinical development of novel protein and antibody drugs will occur. Increasing and expanding the understanding of the critical PK and pharmacodynamic parameters will be necessary in order to speed development and to continue to deliver new biological therapeutic agents.

23.1 INTRODUCTION

23.1.1 What are Natural Toxins?

A common misperception among the public is that any product derived from nature is inherently safe. Nothing could be farther from the truth. Some of the compounds that are most toxic to humans and other mammals occur in nature. History is rife with stories of murder and poisonings from natural toxins, from the death of Socrates via ingestion of poison hemlock (coniine alkaloids from *Conium maculatum*) in 399 BC to the 1978 murder of Bulgarian writer Georgi Markov with an umbrella outfitted with a ricin-filled pellet.

For the sake of this chapter, natural toxins are defined as potentially harmful chemicals produced by living organisms, such as plants, animals, fungi, and algae, or those found naturally occurring in the environment, such as toxic metals. Of course, the

Paracelsan tenet notes that all substances are potentially poisonous depending on the dose. Here, we will consider representative, small-molecule compounds most commonly associated with severe adverse reactions and death.

The production of natural toxins by living organisms is most often the result of secondary metabolism of natural products. Natural toxins may be ingested, inhaled, or absorbed through the skin. Of greatest concern is that natural toxins may enter the food supply at many different points and may be ingested by animals or humans, therefore representing a threat to human health. Increasing attention is also being given to toxic mold contamination of buildings and the risks of inhaled natural toxins.

Over decades, there have been reports on the acute, chronic, and late effects of exposure to natural toxins in both isolated communities and across large populations. Moreover, there have been correlations of their consumption and disposition with late effects of exposure, such as increased risk of cancer from aflatoxins [1]. As a result, there has been much interest in understanding the mechanisms of absorption, distribution, metabolism, and excretion of these compounds and minimizing exposure.

Given the relevance of natural toxins in human health, much attention has been given to identify their sources and understand their effects on the human body. Organizations such as the World Health Organization (WHO), International Program on Chemical Safety (IPCS), US Food and Drug Administration (FDA), and the American Association of Poison Control Centers will commonly issue warnings on toxicology and poisoning trends as well as emergency management of adverse effects of natural toxins.

In the following chapter, we discuss some examples of natural toxins, their sources, and notable mechanisms of metabolism and excretion that influence the toxicity of these chemicals.

23.2 AFLATOXINS

Aflatoxins are the most studied of all fungal toxins or mycotoxins. Aflatoxins are produced primarily by two fungal species, *Aspergillus flavus* and *Aspergillus parasiticus*. These organisms are common saprophytes and opportunistic pathogens with high occurrence in tropics or semitropic regions [2]. Aflatoxins are by-products of fungal metabolism with the major types of metabolites aflatoxin B₁ (AFB₁), aflatoxin B₂, aflatoxin G₁, aflatoxin G₂, and aflatoxin M₁ [2]. Aflatoxins are detected occasionally in milk, cheese, corn, peanuts, cottonseed, Brazil nuts, walnuts, pistachios, pecans, almonds, figs, spices, and a variety of other foods and feeds. Milk, eggs, and meat products are sometimes contaminated because of animal consumption of aflatoxin-contaminated feed. However, the materials with the highest risk of aflatoxin contamination are corn; cereals such as rice, groundnuts, and peanuts; and cottonseed [2].

Factors contributing to the presence or production of mycotoxins in foods or feeds include storage, environmental, and ecological conditions, particularly high humidity environments that encourage growth of *Aspergillus* species normally found in soil [3]. Mycotoxicoses in humans or animals are characterized as food- or feed- related, non-contagious, nontransferable, noninfectious, and nontraceable to microorganism other than fungi [3].

Aflatoxins were originally identified in 1960 as the cause of the death of thousands of turkeys due to hepatic necrosis [4]; their feed was identified as the source of the toxin. To date, the largest case of aflatoxicoses reported in humans occurred in western India in 1974, resulting in 397 recognized cases and 106 deaths [5]. However, additional outbreaks have been reported throughout the world, some examples include Eastern and Central provinces of Kenya in 1981 and most recently, in 2004, where the outbreak resulted from widespread aflatoxin contamination of locally grown maize [6]. The incidence of aflatoxin-driven outbreaks often generates concern about the safety of those exposed and the rate at which neighboring developments show the symptoms. For every symptomatic case of aflatoxicosis identified, several other persons likely were exposed and might face future adverse health consequences. Thus, there is a need to execute routine food inspections to ensure food safety and local education and assistance to ensure that foods such as maize are harvested correctly, dried completely, and stored properly.

Aflatoxin exposure can result in acute aflatoxicosis (poisoning caused by ingestion of high levels of aflatoxin) often manifested as severe, acute hepatotoxicity. Among the early symptoms of hepatotoxicity include anorexia, malaise, and low grade fever. After the acute exposure, the symptoms progress to lethal hepatitis with vomiting, abdominal pain, jaundice, fulminant hepatic failure, and death [7]. In contrast, chronic aflatoxicosis (poisoning caused by chronic ingestion of low to moderate levels of aflatoxin) typically presents with impaired food conversion and slow growth. In addition to aflatoxicosis, aflatoxin exposure can lead to carcinogenesis, particularly hepatocellular carcinoma [1,8,9] as recently reviewed in Ref. 10).

A somewhat controversial approach to prevent aflatoxin exposure via corn and peanuts has been undertaken by the international agribusiness firm Syngenta with the introduction of their Alfa-Guard product. Alfa-Guard is a hulled barley delivery system for spores of a non-aflatoxin-producing strain of *A. flavus* that actively competes for growth by toxic *A. flavus*. The product originated in the US Department of Agriculture's Agricultural Research Service with the work of microbiologist Joe Dorner at the National Peanut Research Laboratory in Dawson, GA.

Despite all of our knowledge on the symptoms and detection of aflatoxin poisoning, it is likely aflatoxins will continue to be a public health problem until appropriate storage methods for food are implemented worldwide. But even in areas of the world with ideal crop storage conditions, *A. flavus* may be unavoidable. The most critical public health approach is continued monitoring of food products for aflatoxins and vigilant surveillance and detection of aflatoxin exposure.

23.2.1 ADME of Aflatoxins

The primary route of absorption of aflatoxins is via ingestion of contaminated food. However, aflatoxins can be found in the dust of contaminated grains and inhalation has been associated with increased risk of lung cancers [11].

Aflatoxins are a classic example of natural toxins that must undergo metabolism to exert their untoward effects. In fact, this theme is common among microbial and plant-based xenobiotics that are toxic to mammals [12].

Aflatoxin activation is mediated via cytochrome P450s (CYPs). Initial debate focused on whether CYP3A4 is the dominant enzyme for AFB₁ metabolism [13,14] relative to the contribution of CYP1A2 [15]. A later study from Gallagher and

colleagues suggested that CYP3A enzyme(s) are capable of AFB₁ oxidation at relatively high substrate concentrations; however, CYP1A2 appears to be the high affinity isoform that is active at lower substrate concentrations when examined in human liver microsomes [16,17]. However, a more recent study on AFB₁ metabolism indicates a predominant role of CYP3A4 for AFB₁ disposition in human liver [18]. In lung cells transfected with cDNA expression constructs for CYP1A2 or CYP3A4, both were capable of AFB₁ activation at low substrate concentrations [11].

Among AFB₁ biotransformation products, activation to the reactive aflatoxin B₁-8,9-epoxide (AFBO) is necessary to exert its hepatocarcinogenic effects, since AFBO binding to cellular DNA, is highly correlated to the carcinogenic potency of AFB₁ [16]. Studies of aflatoxin metabolites have demonstrated covalent binding of AFB₁ to DNA as the AFB₁-N⁷-guanine adduct, 2,3-dihydro-2-(N⁷-guanyl)-3-hydroxy AFB₁ [19]. These adducts can cause G > T transversions and other mutations that lead to tumor formation [20].

In addition to DNA adduct formation, AFBO can also bind other proteins and critical cellular nucleophiles [10]. An example of AFB₁ binding proteins is albumin, the major transporter of AFB₁ in blood [21]. Serum AFB-albumin adducts, are associated positively with hepatocellular carcinoma in humans [22], and analysis of serum adducts has also indicated a positive correlation between dietary AFB₁ exposure and serum AFB₁-albumin adducts [23].

Another example of a toxic adducts is the interaction of AFB₁ with the signal recognition particle (SRP), which acts as an escort for polyribosomes with signal peptides to be transported and bound to the cytoplasmic face of the endoplasmic reticulum (ER) during protein targeting [24]. The interaction of AFB₁ with SRP is now known to generate structural alterations to prevent biosynthesis and translocation of secretory proteins that are important components of the plasma membrane, gap junctions, and intercellular matrix. Singh *et al.* [25] hypothesize that these interactions could disturb cell-to-cell communication and contribute to tumorigenesis.

Aflatoxins are metabolized in liver to oxidized derivatives, including AFBO and AFM₁, that are secreted in the bile and excreted in urine, with a small proportion (about 1% of the ingested dose) being activated through the epoxide to form covalent adducts with DNA [8]. In humans and most animals, the principal route of AFB₁ detoxification is through conjugation with endogenous glutathione (GSH), a reaction catalyzed by glutathione-S-transferases (GST) [10]. Circumstantial evidence is suggestive that GST disposition of aflatoxin metabolites plays a major role in determining the sensitivity of cells to AFB₁ [26]. Essigmann *et al.* [27] first evaluated the possibility of detecting DNA adducts caused by AFB₁ ingestion in human urine, with great success. Since then, detection of DNA adducts or AFBO-albumin complexes in the urine have been a reliable marker for the presence of aflatoxin metabolites.

23.3 ARISTOLOCHIC ACID

Aristolochic acid (AA) is a chemical found in the extract of the plant *Aristolochia fangchi* [28]. Usually, AA is a mixture of structurally related nitrophenanthrene carboxylic acids, with 8-methoxy-6-nitro-phenanthro-(3,4-*d*)-1,3-dioxolo-5-carboxylic acid I known as *aristolochic acid I* (AAI) and the demethoxy analog also known as *aristolochic acid II* (AAII) [29]. For many years, AA was utilized for a variety of

treatments summarized elsewhere [29,30] until it was found that the use of herbal drugs containing AA can cause permanent kidney damage, including end-stage kidney failure, requiring dialysis or kidney transplantation, and cancer associated with the urinary tract.

As a result, in 2001, the FDA released a list of compounds containing AA (<http://www.fda.gov/Food/DietarySupplements/Alerts/ucm095297.htm>) [31]. Moreover, despite the long use of AA in herbal remedies for the treatment of numerous symptoms [29], it was not until the early 1990s when cases of advanced renal failure were reported in Belgium, where it was reported in 1991 that consumption of AA in herbal preparations inadvertently included in slimming pills had a correlation with Chinese herb nephropathy (CHN), a type of progressive renal fibrosis [32,33]. In addition to this incident, AA-driven DNA adducts have also been correlated with Balkan endemic nephropathy patients [34]. Once the role of AA was identified as the cause of CHN, the disorder was then proposed to be referred to as AA nephropathy [35].

In addition to the nephrotoxic effects of AA, correlation with the effects of this toxin in carcinogenesis and mutagenesis [36,37], and with the formation of AA DNA adducts [38], has also been demonstrated. More specifically, the activation of AA to AAI has led to various reports indicating that the AAI-driven DNA adducts are the main cause of malignant transformation [29,30] by inserting an A > T mutagenic transversions affecting adenines of codon 61 of the H-Ras mouse gene [37] or purines in the human tumor suppressor p53 gene [39]. Grollman *et al.* [40] further confirmed the presence of aristolactam-dA and aristolactam-dG lesions in the p53 genes in patients with Balkan endemic nephropathy (EN), defined in this chapter as a chronic tubulointerstitial disease frequently associated with urothelial carcinomas of the upper urinary tract. The authors cite the source of the exposure as *Aristolochia clematitis*, a plant endemic to wheat fields of the region. Consumption of baked breads made from grains contaminated with low levels of *A. clematitis* is believed to be responsible for this chronic disease.

23.3.1 ADME of Aristolochic Acid

AA is primarily absorbed in the body via oral ingestion, either via contaminated grain or in weight-loss diet pills containing extracts of *A. fangchi* [41]. Given that AA is predominantly metabolized by hepatic CYP1A2, the kidney and urinary tract are the predominant sites of toxicity [30]. More specifically, there is also evidence that epithelial cells of the proximal tubule are the primary cellular target of AA [42]. Therefore, the liver, kidney, and transitional uroepithelial cells are the main tissues in which AA metabolites are distributed.

In vitro studies, under anaerobic conditions, have suggested that the most important human enzymes activating AA to AAI are hepatic microsomal CYP1A2, renal microsomal NADPH:CYP reductase [43], hepatic and renal cytosolic NAD(P)H:quinone oxidoreductase (NQO1), as well as cyclooxygenase (COX), which is highly expressed in the urothelial tissue [28]. Of all the activating enzymes mentioned above, one of the most efficient AA activating enzymes is NQO1, ubiquitously present in all tissue types [30].

On the other hand, there is also evidence that under aerobic conditions, hepatic microsomes from rats and humans demethylate AAI to form AAIIa [44]. AAIIa (8-hydroxy-6-nitro-phenanthro-(3,4-*d*)-1,3-di-oxolo-5-carboxylic acid) is the nontoxic

derivative of AA. *In vivo* studies by Xiao and colleagues [45] suggested that hepatic CYP1A enzymes, specifically CYP1A2, also play a critical role in detoxification and prevention of AAI-induced kidney injury. Therefore, depending on the systematic conditions, CYP enzymes can play the role of AA activator or AAI excretion.

AA metabolites are excreted in urine. As described above, the main effects of AAI in the human body is the formation of DNA adducts in animals and humans. As a result, AA–DNA adducts have been validated and used as biomarkers of exposure to AA and to investigate the mutagenic and carcinogenic potential of AA. The major AA–DNA adducts found in rodents exposed to AA and in patients suffering from AAN were identified as 7-(deoxyadenosin- N^6 -yl) aristolactam I (dA-AAI), 7-(deoxyguanosin- N^2 -yl) aristolactam I (dG-AAI), and 7-(deoxyadenosin- N^6 -yl) aristolactam II (dA-AAII) [30,46].

23.4 ARSENIC

Arsenic (As) is a highly poisonous metallic element. Inorganic As occurs naturally in the environment and exposure can occur via leaching from geological formations and occupational exposure such as in mining activities, metal processing, and application of pesticides [47].

As exposure can occur from food, air, and water, but the major chronic As exposure comes from the most precious and needed element for survival, water. Among the arsenic species identified in natural water are inorganic arsenite (As^{III}), arsenate (As^{V}), monomethylarsonic acid (MMA^{V}), monomethylarsonous acid (MMA^{III}), dimethylarsinic acid (DMA^{V}), and dimethylarsinous acid (DMA^{III}); As^{III} and As^{V} are by far the most toxic to humans [48]. Therefore, it is vital to regulate the levels of As in water sources all around the world as a method to control As poisoning (arsenicosis) throughout the world. As exposure is correlated with several types of cancer such as the skin, bladder, and lung, reviewed in detail by Kapaj and colleagues [47] and others [49]. In addition to cancer, As also has effects in memory and intellectual functions, cardiovascular disease, respiratory system diseases, and diabetes among others [47].

The mechanisms by which As causes carcinogenicity is by exerting either genotoxic effects (e.g., chromosomal abnormalities, oxidative stress, and gene amplification) or nongenotoxic effects (e.g., altered growth factors, enhanced cell proliferation, and altered DNA repair) as reviewed in detail elsewhere [50].

23.4.1 ADME of Arsenic

As can be absorbed through either the respiratory or the digestive system. Human inhalation exposure to inorganic arsenic can occur through occupational exposure (e.g., coal-fired power plants) or during cigarette smoking [51]. The process starts when As particles are first deposited in the lungs, where it is later absorbed into the bloodstream, depending on the solubility of the chemical form of As. Evidence of As absorption can be detected in the urine, making possible to determine the As exposure in humans as reported by Offergelt *et al.* [52], Yager *et al.* [53], and others.

After the absorption of As through either the respiratory or digestive system, As metabolites enter the bloodstream, to be distributed to the different parts of the body. Exposure to As leads to an accumulation of As in tissues such as skin, hair, and nails,

resulting in various clinical symptoms such as hyperpigmentation and keratosis [47]. The analysis of Scottish and Japanese individuals after long-term chronic exposure showed that As can also accumulate in bone, teeth, muscle, brain, and heart among other organs as summarized in Ref. 48.

In humans, As is excreted as both methyl arsenic (MAs) and dimethyl As (DMA) being the second the main metabolite excreted by the body and detected in the urine of exposed patients [54,55]. The metabolism of arsenic is characterized in many species by two types of reactions: (1) reduction of pentavalent to trivalent arsenic and (2) oxidative methylation reactions in which trivalent forms of arsenic are sequentially methylated to form mono-, di-, and trimethylated products using *S*-adenosyl methionine (SAM) as the methyl donor and GSH as an essential cofactor [51].

Each oxidative methylation reaction is preceded by reduction of arsenic from the pentavalent to the trivalent oxidation state. These reactions are catalyzed by a cytosolic enzyme, arsenic (+3 oxidation state) methyltransferase (As3mt), which uses *S*-adenosylmethionine (AdoMet) as a methyl group donor and requires a dithiol-containing reductant (e.g., thioredoxin) for catalysis [56,57].

Urinary excretion of arsenic begins when arsenic metabolites in the blood are removed by the kidneys about 5 h after ingestion [54]. Early reviews in the field have reported that the arsenic metabolites entering the bloodstream are excreted in several forms, including arsenite (As+3), arsenate (As+5), methyl dimethylarsinic acid (DMAA), and other organically bound arsenic compounds [54]. As can also be excreted through the skin, nails, hair, and sweat but to a far lesser quantitative extent.

While arsenic is considered toxic during acute or chronic oral or inhalation exposure, intravenous arsenic trioxide (As₂O₃) was investigated in China during the early 1990s as a treatment for acute promyelocytic leukemia (APL) [58]. The same research team that had popularized the use of all-*trans*-retinoic acid for APL had been investigating traditional Chinese remedies and identified an antileukemia component as arsenic trioxide [59]. The anticancer effects of arsenic trioxide appear to be due in part to inducing BH-3 family proapoptotic mediators [60]. Second-generation organic arsenicals may continue to have efficacy in cancers that have become resistant to arsenic trioxide [61].

23.5 SELENIUM

Of all the natural products to which humans are exposed, not all can be classified as either beneficial or toxic. This is the case for the trace element Selenium (Se), which can be both beneficial or toxic depending on the exposure and/or doses administered. Se is an essential trace element for humans, animals, and some bacteria [62].

Se is considered essential due to its association with proteins, known as *selenoproteins* [63]. Selenoproteins have biological functions in oxidoreductions, redox signaling, antioxidant defense, thyroid hormone metabolism, and immune responses [64]. Given the important role of selenoproteins in physiological functions, selenoproteins possess a strong correlation with human diseases such as cancer, Keshan disease, virus infections, male infertility, and abnormalities in immune responses and thyroid hormone function [64].

While an essential nutrient, Se can also be toxic depending on the exposure levels. For example, Se compounds at low concentration may have protective anticarcinogenic

properties, whereas at higher concentration, they can be genotoxic and possibly carcinogenic [65]. Chronic toxicity of selenium in humans results in a condition termed *selenosis*, characterized by hair and nail loss and brittleness, gastrointestinal problems, skin rash, garlic breath odor, and nervous system abnormalities [66]. Other related toxic effects caused by Se are disruption of endocrine function, including synthesis of thyroid hormones and growth hormones, and insulin-like growth factor metabolism [67]. The mechanism of Se toxicity has not been clarified but is mostly attributed to its ability to induce oxidative stress both *in vitro* and *in vivo* [62,68].

Se exists mostly in organic forms in normal diets. Organic Se is present in foods mainly in the form of selenomethionine, selenocysteine, and Se methylselenocysteine, whereas inorganic Se either as selenite or as selenate occurs much less frequently and in very low amounts [69]. Of the organic forms, selenomethionine is the predominant form in most Se-rich diets. Both organic and inorganic forms of Se appear to be utilized with similar efficacy in the body to produce selenoproteins [70]. Given that Se is a nutrient whose deficiency and toxic concentrations are very close to each other, it is important to know about its abundance or deficiency in food and diet to establish the right balance of Se in humans and animals [67] and to establish clear parameters of the maximum tolerated doses to benefit from it and also prevent its toxic effects.

23.5.1 ADME of Selenium

The main source of Se is food, and the content of Se can vary much depending on the geographical location, seasonal changes, protein content, and food processing [67]. Se *exposure* occurs mostly through ingestion of Se-containing foods, with much of dietary Se coming from nuts, cereals, meat, fish, and eggs. The levels of Se in different foods and beverages vary and have been reviewed in detail in Ref. 67. Se bioavailability strongly depends on the chemical form of Se found in food, and generally, organic forms of Se are more bioavailable than the inorganic forms [67,71]. Approximately 80% of dietary Se is absorbed, with wheat and meats the most important Se dietary sources [67]. The absorption of Se occurs in the small intestine as evaluated in many animal models by numerous researchers in the field.

Following Se absorption, it is then distributed throughout the body where Se can be located in the skeletal muscles, although organs such as the kidneys, testes, and liver have the highest relative concentration of Se. In contrast, cells that reveal a higher consumption of Se are those of the immune system, erythrocytes, and platelets [67].

Inorganic forms of selenium (selenite and selenate) are reduced by GSH to generate hydrogen selenide (H_2Se) intermediates that later become incorporated into selenoproteins. Organic forms of Se can also become the H_2Se intermediate, where H_2Se is the intermediate compound between the reductive metabolism of Se and its methylation pathway [69]. Selenium compounds such as selenite, selenodiglutathione, and selenocystine are substrates for *antioxidant enzymes* thioredoxin reductase, thioredoxin, and glutathione peroxidase among others [72]. A by-product from Se metabolism is the formation and accumulation of reactive oxygen species (ROS), which are considered as a source of Se-driven toxicity in the form of DNA damage as reviewed by [69,73,74].

Se is eliminated from the body primarily via the urine, although significant losses via feces also occurs and low amounts of Se are also lost through the skin and respiration [67]. More specifically, there are studies confirming that Se excretion can be rapidly

detected in the urine, where 50–78% of the ingested element is excreted [75], and the levels of secreted Se change depending on the intake of Se in an individuals diet.

23.6 IBOTENIC ACID AND MUSCIMOL

Amanita muscaria is a mushroom with a rich history of use by shamanic cultures of Siberia and northeast Asia. Known also as fly agaric for its use as an insecticide, *A. muscaria* contains the alkaloids ibotenic acid and muscimol and is easily recognizable owing to its red cap with white spots. Saar [76] has described the religious use of *A. muscaria* and English language accounts extending back to the 1700s describe an unusual practice of metabolic significance. A Swedish colonel, Philip Johan von Strahlenberg, held as a prisoner by the Koryak tribe of Siberia wrote in 1730 of his experiences:

“Those who are rich among them, lay up large provisions of these mushrooms, for the winter. When they make a feast, they pour water upon some of the mushrooms, and boil them. Then they drink the liquor, which intoxicates them. The poorer sort . . . post themselves, on these occasions, round the huts of the rich, and watch the opportunity of the guests coming down to make water; and then hold a wooden bowl to receive the urine, which they drink off greedily. . . , and by this way they also get drunk [77]”

The practice, substantiated by George Steller in 1774, owes to the decarboxylation of ibotenic acid to muscimol and a much higher urinary concentration of muscimol than in the mushrooms. Muscimol is an agonist for GABA(A) receptors and produces a lucid dreamlike state that can be perceived as either desirable or disturbing depending on the context. Often mischaracterized as a hallucinogen, muscimol is better described as a deliriant. The receptor specificity of muscimol has led to its use as a radioligand for defining GABA(A) receptors. The parent compound, ibotenic acid, is also a N-methyl-D-aspartate (NMDA) glutamate receptor agonist and is responsible for jerky muscle movements often accompanying accidental ingestion of the mushrooms. In the laboratory setting, ibotenic acid can be used to specifically lesion parts of the brain owing to its excitotoxic effect at NMDA receptors.

Ingestion of *A. muscaria* is rarely fatal. According to the American Association of Poison Control Centers, 61 cases of *A. muscaria* poisonings were reported in 2009.

23.7 α -AMANITIN

While this chapter focuses on small-molecule toxins, the previous discussion of *Amanita* species necessitates some treatment of this classic peptide hepatotoxin. Unlike mushrooms that produce ibotenic acid and muscimol, other species of *Amanita*, most notably not only *Amanita phalloides* but also *Amanita virosa* and *Amanita bisporigera*, are recognized for their production of the cyclic octapeptide, α -amanitin.

Work on the chemistry of toxic “death cap” mushrooms can be traced by to Heinrich Wieland, 1927 Nobel laureate in chemistry for work on the bile salts. Wieland’s student at Munich (and later son-in-law), Feodor Lynen, conducted his 1937 PhD dissertation work entitled “On the Toxic Substances in *Amanita*,” and Wieland’s laboratory later

crystallized the substance in 1941. Lynen went on to investigate the biochemistry and synthesis of cholesterol and fatty acids, work for which he shared the 1964 Nobel Prize in Physiology or Medicine with Konrad Bloch. Work on the amatoxins and related phalloidins was instead undertaken by Heinrich's son Theodor and nephew Ulrich, respectively. While phalloidin exerts toxicity by triggering depolymerization of F-actin, it requires hepatic bioactivation for maximum toxicity. Fluorescent conjugates of phalloidin are used widely today for microscopic imaging of cellular actin networks.

Theodor Wieland worked tirelessly on the chemistry and biochemistry of amatoxins and was the first to separate the α , β , and later γ isoforms by solid-phase electrophoresis [78], a method later used to demonstrate isozymes among enzyme families. The Italian group of Stirpe and Fiume were first to demonstrate in 1967 that α -amanitin rapidly and potently inhibited RNA synthesis [79,80]. Lindell *et al.* [81] later showed in 1970 that the proximal target of α -amanitin was nuclear RNA polymerase II, the RNA polymerase responsible for messenger RNA synthesis. In fact, the selectivity of α -amanitin for the type II polymerase is used to distinguish between the biosynthetic activities of RNA polymerase I (primarily ribosomal RNAs) and III (primarily transfer RNAs).

Symptoms of amatoxin poisoning do not usually present until 6–8 h after ingestion, with severe abdominal cramps, vomiting, and gastrointestinal bleeding that gives rise to hepatic and renal failure [82]. Reports vary based on amount ingested and time of treatment initiation, but most sources cite a 15% fatality rate within 10 days of *A. phalloides* ingestion. Liver transplantation can be curative but is usually not practical. One challenge in antidote management is that α -amanitin undergoes enterohepatic recirculation.

European literature had suggested the potential utility of an intravenous preparation of partially purified extract of milk thistle (*Silybum marianum*), silibinin hemisuccinate (Legalon SIL). This intravenous preparation is produced by Madaus AG and is currently only available in Europe. Two hepatoprotective mechanisms of action are possible: the silibinin compounds may inhibit reuptake of the toxin by intact hepatocytes and/or competitively interfere with glucuronide hydrolysis. Several highly publicized and successful treatment cases in the United States led to an initiation of an open-label clinical trial [83]. The outcome of the ongoing trial is likely to influence the regulatory status of Legalon in the United States.

The reader is referred to an outstanding review in *Science* by Theodor Wieland in 1968 [84] that exhaustively addresses the toxins of all *Amanita* species, from ibotenic acid and muscimol to amatoxins and phalloidotoxins.

23.8 PYRROLIZIDINE ALKALOIDS

Over 350 pyrrolizidine alkaloids can be found in numerous plant species, typically considered noxious weeds, but may also be contaminants of honey, milk, and grains. The most common historical exposure to pyrrolizidine alkaloids has been with herbs purported to have medicinal value. Comfrey, for example, is still sold for making medicinal teas yet is a well-known source of the alkaloids, symphytine, and echimidine [85].

Pyrrolizidine alkaloids are bioactivated by CYP to cause veno-occlusive disease of the liver and cirrhosis after long-term use [11]. This life-threatening disease was first described in 1954 from the ingestion of Jamaican bush tea (*Senecio discolor* and

Crotalaria fulva) but literature reports consistent with this pathology can be found as early as 1920 [86].

CYP3A4 and flavin-containing monooxygenases are responsible for the C- and N-oxidation of pyrrolizidine alkaloids to form the reactive pyrrolic ester and *N*-oxides, respectively.

23.9 GERMANDER (TEUCRIN A)

While pyrrolizidine alkaloids and AA are among the best known plant toxins historically, some localized cases of hepatotoxic herb exposure appear sporadically. In 1991, use of a French weight loss supplement containing wall germander (*Teucrium chamaedrys*) was associated with seven cases of hepatitis that required hospitalization. Pathology ranged from hyperbilirubinemia and jaundice to hepatic necrosis [87]. The hepatotoxicity of two furan-containing diterpenoid components, teucrin A and teuchamaedryn A, is mediated via CYP3A4 oxidation of the 3-substituted furan to an epoxide [88]. The epoxide is proposed to rearrange to form an electrophilic reactive enedial. Druckova *et al.* [89] used teucrin enedial–albumin adducts to create an antibody probe that revealed 46 protein adduct targets in rats administered with teucrin A. The majority of adducted target proteins were found in the mitochondria and ER, such as those involved in lipid metabolism, energy production, cellular respiration, drug metabolism and clearance, and protein chaperones.

While these incidents are infrequent, herbal folkloric use of germander species continues today. A February 2012 case report from Istanbul detailed a case of vomiting and moderate hepatic injury in two-month-old twin sisters who had been given 10 mL of polygermander tea (*Teucrium polium*) added daily to their infant formula for colic [90]. The infants recovered with supportive intravenous fluids and vitamin K administration and were discharged after five days. The continued occurrence of these and other cases of “natural” hepatotoxicity should serve as warning to clinicians to query patients about alternative medicine use on presentation with liver disease of unknown cause [11].

23.10 MACROCYCLIC TRICHOTHECENE (MT) MYCOTOXINS

This class of compounds has become of increasing toxicological importance due to the appreciation of the so-called toxic black mold in human diseases. *Stachybotrys chartarum* and *Stachybotrys chlorohalonata* can colonize water-damaged building materials and cause indoor air exposure to macrocyclic trichothecenes (MTs). These and other species can produce one or more sesquiterpene trichothecenes whose presence can be quantified in indoor air of contaminated buildings. The most common trichothecenes are verrucarins B and J; roridin E; satratoxins F, G, and H; and isosatratoxins F, G, and H.

These compounds are broadly cytotoxic in the nanomolar range and had originally been evaluated by the US National Cancer Institute for potential anticancer activity but their lack of selectivity caused their study to be discontinued. The most noteworthy structural features in their toxicity are the presence of an epoxide moiety (present in all but three MTs) and a diene in the sesquiterpene skeleton. Little work has been done on

the metabolism and excretion of MTs, but it is likely that phase I and phase II enzymes are involved in activation and detoxification of these increasingly relevant toxins.

Work in the yeast *Saccharomyces cerevisiae* indicates that mitochondrial protein synthesis is the target of the trichothecene, trichothecin [91,92]. Several of the compounds are known to cause respiratory symptoms by activating cytokine secretion in human macrophages [93].

ACKNOWLEDGMENTS

The authors wish to thank Heather S. Shaw, MD, MPH, (Durham VA Medical Center) for guidance on public health and epidemiological literature. The authors also wish to thank readers of the Terra Sigillata blog at the CENTral Science network of the American Chemical Society's *Chemical & Engineering News* who responded to a call for suggestions on the most relevant naturally occurring toxins (<http://cenblog.org/terra-sigillata/2011/07/21/naturally-toxic-crowdsourcing/>).

24.1 INTRODUCTION

During pregnancy, progesterone, a steroidal sex hormone, plays an important role in the discontinuation of female menstrual cycle and in the embryogenesis. The increase in progesterone levels starts during ovulation, continues to increase during pregnancy, and

helps in the development of the uterine lining for implantation of the fertilized egg. In reverse, decreased progesterone levels are associated with the risk of miscarriage. The levels of progesterone during menstrual cycle and in the first trimester of pregnancy are controlled by ovaries, but as the placenta grows (ninth–tenth week), it takes over this role of the ovary and maintains progesterone during pregnancy.

The changes in levels of progesterone and other associated hormones are linked to changes in physiological conditions of the pregnant mother, such as increase in blood plasma volume, extracellular fluids, cardiac output, renal flow, white blood cells, platelet and decreases in albumin, hemoglobin, urea, creatinine, and so on. These physiological adaptations are to favor the development of the fetus, but this also results in alterations to drug-metabolizing enzymes (DMEs) and xenobiotic transporters, thereby affecting pharmacokinetics of drugs in the body and leading to increased potential for side effects.

During pregnancy, human placenta functions as both a barrier and a transport organ, helping in exchange of nutrients and oxygen as well as waste products between the mother and the fetus. These functions are assisted by transporter proteins expressed on the placental syncytiotrophoblasts, which have differential localization in the maternal-facing brush border membrane and fetal-facing basal membrane. The transporters expressed on maternal-facing brush border membrane facilitate the entry of xenobiotics from mother to fetus. The passage of nutrients and xenobiotics across the placental barrier is chemically regulated by enzymes such as hydrolases, transferases, oxidoreductases, lyases, and isomerases. These enzymes have been implicated in xenobiotic metabolism, the generation of reactive metabolites, and in rare cases, birth defects and teratogenicity.

The purpose of this chapter is to review the aspects of transport, metabolism, and clinical implications of administered drugs during pregnancy. It covers the nature of physiological changes occurring during pregnancy, types of transporters expressed, differential enzymes present, and clinical implications of these factors on drug therapy for the pregnant mother and fetus.

24.2 PHYSIOLOGICAL CHANGES OCCURRING IN PREGNANT MOTHERS AND THEIR INFLUENCE ON DRUG DISPOSITION

The physiology of a pregnant woman is significantly different from that of a non-pregnant woman. Practically, physiological changes begin in early gestation and are most pronounced in the third trimester of pregnancy. Some of these are normalized within 24 h of delivery, while others return to normal in 12 weeks after delivery [1]. Table 24.1 lists the nature of physiological changes in the body through the pregnancy period and postpartum. Major changes occur within the gastrointestinal tract (GIT), cardiovascular, renal, and hepatic systems. These changes have the potential to influence absorption, distribution, metabolism, and excretion (ADME) of drugs. A few examples are included in Table 24.2.

24.2.1 Physiological Changes in the Cardiovascular System

Cardiovascular changes occurring during pregnancy include alterations in cardiac output, blood volume, blood pressure, extracellular fluid space, plasma albumin, and

TABLE 24.1 Physiological Changes during Pregnancy

Physiological Parameter	Nonpregnant Women	Pregnant Women	References
BP	SBP = 120 ± 9.8 mm Hg DBP = 80.0 ± 7.2 mm Hg	SBP = 119.6 ± 9.8 mm Hg DBP = 65.0 ± 7.2 mm Hg	2
Cardiac output	2.90 ± 0.17 L/min	6.7 L/min at 8–11 wk and 8.7 L/min at 36–39 wk	3
Blood plasma volume	4–5 L	Increase by 40–50%	3
RBC count	4.2–5.4 million cells/mL	Increased by 20–30%	3
Hb	10.5–13.5 g/dL	Decrease in Hb due to relatively less increase in RBC count in comparison to blood plasma volume	4,5
Alkaline phosphatase, plasma	26–110 IU/L	Increased during pregnancy	6
Platelets count	$200\text{--}600 \times 10^9$ cells/L	Unchanged/slightly increased	3
Urine creatinine	37–250 mg/dL	Decreased in pregnancy	3
Albumin	24–31 g/L	Decreased in pregnancy	6
Fasting glucose	3.0–5.0 mmol/L	Unchanged in pregnancy	3
Alanine	407 ± 66 μ mol/L	10–20 wk = 321 ± 58 μ mol/L, 30–40 wk = 321 ± 58 μ mol/L	7
Citrulline	43 ± 11 μ mol/L	10–20 wk = 24 ± 6 μ mol/L, 30–40 wk = 29 ± 9 μ mol/L	7
Arginine	79 ± 10 μ mol/L	10–20 wk = 51 ± 10 μ mol/L, 30–40 wk = 39 ± 8 μ mol/L	7
Ornithine	50 ± 4 μ mol/L	10–20 wk = 23 ± 5 μ mol/L, 30–40 wk = 21 ± 4 μ mol/L	7
Total bilirubin	0.0–1.0 mg/dL	Decreased during pregnancy	6

Abbreviations: BP, blood pressure; SBP, systolic blood pressure; DBP, diastolic blood pressure; Hb, hemoglobin; RBC, red blood cells; SBP, systolic blood pressure; wk, weeks.

RBC count. Cardiac output rises by 30–50% by the end of the second trimester and remains the same until delivery. Likewise, blood volume increases progressively from six to eight weeks to reach a maximum at 32–34 weeks with little change thereafter, with overall increase being 40–50% during normal pregnancy [23–26]. The increase in blood and total body water volumes alter the volume of distribution of various drugs. These changes affect drug disposition and elimination, as well as the terminal elimination half-life [27]. Albumin content has been shown to decrease, while there is increase in α 1-acid glycoprotein during pregnancy. These changes lead to alterations in protein binding of drugs and result in increase in their plasma concentration beyond the therapeutic window. For example, diazepam, phenytoin, and sodium valproate have significantly elevated free fractions in the last trimester because of the decrease in the

TABLE 24.2 Select List of Drugs Showing Alterations in Pharmacokinetics and Metabolism during Pregnancy

Drug	Gestational Age	ADME	Enzyme/Transporter	Significance	References
Methadone	27–30 wk	Increased metabolism and decreased absorption	NS	Higher elimination rate constant and lower half-life compared to nonpregnant controls	8
Caffeine	Second and third trimesters	Decreased metabolism	CYP1A2	Decrease in clearance	9
Nelfinavir	31–36 wk	Increased metabolism	Induction of hepatic CYP3A4 or inhibition of CYP2C19	Safety and efficacy (therapeutic drug monitoring)	10
Indinavir	Correlation between during pregnancy and postpartum	Increased metabolism	NS	Warrant dosage adjustment during pregnancy	11
Cotinine	NS	Increased metabolism	CYP2A6	Clearance increased by 140% and half-life by 50%	12
Lamotrigine	Second and third trimesters	Drug distributed in fetus	NS	Leads folate deficiency that finally results in teratogenic effects	13
Labetalol	NS	Increased metabolism	UGT1A1, UGT2B7	Clearance increased	14
Metoprolol	Third trimester	Increased metabolism	CYP3A4	Clearance increased	15,16
Nifedipine	Third trimester	Increased metabolism	CYP3A4	Clearance increased	17
Phenytoin	NS	Altered absorption or metabolism	NS	Seizures appear	18,19
Citalopram	20, 30, and 36 wk	Increased metabolism	NS	Dose adjustment required	20
Escitalopram	20, 30, and 36 wk	Increased metabolism	NS	Dose adjustment required	20

albumin content. The increase in body weight during pregnancy further results in a decrease in dose/kg of administered drugs and leads to a significant lowering of a drug's steady-state concentration with resultant suboptimal treatment.

24.2.2 Physiological Changes in the Gastrointestinal System

Motility disturbances of the GIT are common during pregnancy. These disturbances are largely due to alterations in sex hormone levels, including heartburn, nausea and vomiting, abdominal bloating, and constipation [28]. Among these symptoms, nausea and vomiting have greater influence on absorption and bioavailability of drugs, especially during the first trimester [29]. Also, increase in plasma progesterone concentration during pregnancy corresponds to decrease in gastrointestinal motility, with associated prolonged gastric emptying and intestinal transit times. This may lead to delayed drug absorption and reduced peak concentration [30]. In addition, gastric pH is slightly increased during pregnancy due to the reduced gastric acid secretion, which may affect ionization and absorption of weak acidic and basic drugs [31].

24.2.3 Physiological Changes in the Renal System

Renal physiological changes are characterized by marked vasodilatation that leads to an increase in the glomerular filtration rate (GFR) and renal plasma flow (RPF). These changes are initiated during the first trimester, by the end of which GFR and RPF increase by 50% and 60–80%, respectively. Apparently, there is higher increase in RPF in comparison to GFR, resulting in a significant decrease in filtration fraction (GFR/RPF). In addition, creatinine clearance is increased during pregnancy, while its production remained unchanged. This results in lowering of serum creatinine. As a fallout of the above conditions, there is increased clearance of polar drugs via kidney during pregnancy, with the likelihood of failure of the treatment [32–34].

24.2.4 Physiological Changes in the Hepatic System

During pregnancy, the mass of the liver is increased up to 50%, which results in a decrease in the per milligram expression of DMEs. In addition, alterations in sex hormone levels also affect expression of different phase I and phase II DMEs. Davis *et al.* [35] found that hepatic microsomal enzymes started rising progressively from the twelfth week of pregnancy and continued till delivery, with a gradual fall to normal levels by the sixth week postpartum. Sulfate conjugation was decreased during pregnancy, and this was attributed to the inhibitory effect of the high levels of estrogen during pregnancy. In a similar manner, inhibitory effects of progestogens on the glucuronide conjugation of drugs were also established [7]. Additional pregnancy-induced changes included decrease in bilirubin and γ -glutamyltransferase and increase in aminotransferases, alkaline phosphate (used in the diagnosis of hepatotoxicity), and 5'-nucleotidase (used in the diagnosis of cholestasis) [6]. Some changes during pregnancy were similar to those observed in hepatotoxicity, for example, increased serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) activity during the third trimester, although this typically remained below the upper margin of normal limit. However, other reports indicate that there were no changes in ALT and AST activity during pregnancy [36–40]. However, their activity increased during labor due to the contractions of the uterine muscles [41,42].

24.3 CHANGES IN TRANSPORTERS DURING PREGNANCY

The efflux [ATP-binding cassette (ABC)] and uptake [solute carrier (SLC)] transporters are altered during pregnancy and ontogeny. The changes occurring at placental and fetal levels are primarily meant to provide nutrition to the fetus and provide protection from undesired xenobiotics and endogenous waste products. This barrier is not absolute, and some of the xenobiotics and drugs do cross and influence the fetus.

24.3.1 Transporters in Human Placenta

Drugs used during pregnancy are for the treatment of either the mother or, to a lesser extent, the fetus. During pregnancy, drug selection is mainly dependent on the ability of the drug to cross the physical barrier between the maternal and fetal compartments. If therapy is needed only for the mother then transfer of drugs through the placenta can lead to toxic effects in the fetus. On the other hand, if the fetus requires therapy, transfer of the drugs from the mother to the fetus becomes an important determinant.

Major functions of the placenta are to transfer nutrients from the mother to the fetus and to eliminate metabolic waste products from the fetus through the mother, which is performed by transporters that are expressed in the maternal-facing brush border membrane and the fetal-facing basal membrane of the syncytiotrophoblasts. These transporters are involved not only in maintenance of the flow of nutrients and macromolecules that are needed for placental function and fetal development but also in the transportation of xenobiotics, including therapeutic agents, environmental pollutants and toxins, and even drugs of abuse. The ABC efflux transporters expressed in placenta are P-glycoprotein (PgP/MDR1/ABCB1), breast cancer resistance protein (BCRP/ABCG2) and multidrug resistance proteins 1–3 and 5 (MRP1–3 and 5/ABCC1–3 and 5). The SLC influx transporters are organic anion transporting polypeptides (OATPs), organic anion transporters (OATs), organic cation transporters (OCTs), monocarboxylate transporters and nucleoside transporters [43–46]. Table 24.3 lists placental transporters along with their drug substrates and their clinical impact on the fetus. The human placental barrier at term, the microstructure of placental barrier, and the main transporter proteins expressed in human placental barrier and their localization are illustrated in Fig. 24.1 [46].

24.3.1.1 ABC Transporters. ABC efflux transporters are located on the maternal-facing and the fetal-facing sides of syncytiotrophoblasts and/or the endothelium of fetal capillaries. These are involved in transport of exogenous and endogenous compounds and metabolites across the placenta, so as to limit the fetal exposure to potential toxins from maternal circulation, thereby protecting it. Drug substrates for this category of transporters include cardiovascular, anticancer, and anticonvulsant drugs; anti-HIV protease inhibitors; and so on. The ABC efflux transporters expressed in placenta are PgP/MDR1/ABCB1, BCRP/ABCG2, MRP1–3 and 5/ABCC1–3 and 5.

24.3.1.1.1 PgP/MDR1/ABCB1. This transporter is a product of the multiple drug resistance (MDR) ABCB1 gene and is expressed in the placental trophoblast layer located in the brush border membrane. PgP is involved in active efflux of lipophilic

TABLE 24.3 Transporters Involved in Drug Transfer Across the Placenta

Transporter	Substrate	Clinical Impact	References
OATP	Streptomycin	Hearing loss in infants	47
Na ⁺ -dependent organic cation transporter	Tetracycline	Deformations in bone and formation of teeth, enamel in infants	48,49
Active transport	Warfarin	Bleeding in fetal brain	50,51
Mrp2	ACE inhibitor	Damage to fetal kidney	52,53
PgP	Glyburide	Active efflux reduces toxicity in fetus	54
<i>mdr1a</i> -/-/ <i>1b</i> -/-	Saquinavir, paclitaxel	16 times more drug required	55
PgP	Avermectin	Protects from cleft palate in fetus	56
PgP	Indinavir	Lower fetomaternal clearance, bidirectional transfer	57
PgP	Vinblastine	Increased maternofetal clearance	56
PgP	Methadone	Active efflux reduces toxicity in fetus	58
PgP	Anthracyclines, taxanes	Decreased exposure to fetus and reduced toxicity	43
PgP	HIV protease inhibitor	Reduced mother to child HIV transmission	59
Passive transport	Ganciclovir	Teratogenic and embryotoxic effects	60
ABC transporters	Antiepileptic drugs	Congenital malformations, minor anomalies, congenital syndrome, and developmental disorders	61
Passive transport	Lidocaine, bupivacaine	Epileptiform discharges, immaturity of the autonomic nervous supply to the cardiovascular system, fetal methamoglobinemia	62,63
Carrier-mediated transport	Metformin	Polycystic ovary syndrome	64,65

substances from the cell. Transport by PgP is unidirectional, and the substrate is effluxed out from the cell due to its asymmetrical membrane topology. Thus, by moving out toxic substances/xenobiotics, PgP protects the fetus from potential toxins that can cross the placenta [66].

The placental expression of PgP is significantly high in preterm as compared to term placenta and gradually decreases with gestational age [67]. Cyclosporine was used to directly evaluate the influence of PgP on transplacental

Figure 24.1 Pictorial representation of term placenta along with the developed fetus, indicating the expression of transporter proteins (BCRP, breast cancer resistance protein; MDR, multidrug resistance protein; MRP, multidrug-resistance-associated protein; NET, noradrenalin transporter; OAT, organic anion transporter; OATP, organic anion transporting polypeptide; OCTN, novel organic cation transporter; SER, serotonin transporter). transfer with a dually perfused human placenta model. The clearance of cyclosporine was increased significantly when it was coadministered with quinidine (a potent PgP inhibitor) [68]. PgP decreased the uptake of rhodamine123 from the maternal to the fetal side, while accelerating elimination of PgP substrates from the fetal side [69]. This perfused placenta model has also been used to demonstrate efflux of the PgP substrate drugs, saquinavir [70], methadone [38], indinavir [58], and prazosin [71]. Interestingly, a reverse pattern was found in the rat, where an increase in Mdr1a and Mdr1b expression was observed with advancing gestation [72].

24.3.1.1.2 BCRP. BCRP expression is very high in the human placenta, suggesting a role similar to PgP in limiting fetal exposure to xenobiotics and facilitating elimination of xenobiotics from the fetal compartment. In membrane vesicles prepared from human term placenta, BCRP transported mitoxantrone [73] and glyburide [74], and the perfused human placenta model revealed BCRP-mediated efflux of glyburide [75] and cimetidine [76]. A role has been suggested for BCRP (and OATP2B1) in regulating placental estrogen synthesis by mediating the concentrations of dehydroepiandrosterone sulfate and estrone 3-sulfate [77]. BCRP and its mRNA expression was twice as high in the preterm (28 ± 1 weeks) relative to the term (39 ± 2 weeks) human placenta [78]. Similar decrease with gestation was also observed in the rat [79].

24.3.1.1.3 MRPs. MRP1 is present in the apical membrane of the placental syncytiotrophoblasts [80] and the human choriocarcinoma cell line BeWo, where it transports unconjugated bilirubin [81] and mediates 2,4-dinitrophenyl-*S*-glutathione efflux [82]. MRP1 expression in BeWo cells is induced by zearalenone, a nonsteroidal estrogenic mycotoxin [83]. Similar to MRP1, MRP2 is also expressed in the apical membrane of the placental syncytiotrophoblasts [84]. The maternal-to-fetal transfer of talinolol is increased by probenecid, an MRP2 inhibitor, demonstrating functional significance in the human placenta [85]. There is increase in placental MRP2 mRNA and the protein with gestation, indicating developmental control of MRP2 in human placenta [84]. MRP3 is localized in the fetal vessel endothelial cells and at lower concentrations on the apical side of the placental syncytiotrophoblasts [80]. MRP5 is expressed at the basal membrane of syncytiotrophoblasts and endothelial cells of the fetal vessels [86]. MRP5 protein expression decreases with pregnancy, with the highest expression in early preterm placenta [86]. The excretion of potentially toxic anions such as bile acids and biliary pigments is performed by the fetus in conjunction with the placenta and the maternal liver. Bile acids and bilirubin are transferred to the maternal blood by MRP1–3 and BCRP [87]. Under physiological circumstances, fetal bile acids and bilirubin are transported across the placenta and taken up by the maternal liver, which eliminates them via MRP2 and bile salt export pump (BSEP).

24.3.1.2 SLC Transporters. These are uptake proteins present in the placenta and are involved in the transportation of nutrients and proteins toward the developing fetus and of potential toxins and endogenous waste toward the maternal side. The SLC

uptake transporters include OATPs, OATs, OCTs, monocarboxylate and nucleoside transporters.

24.3.1.2.1 OATP. These are bidirectional transporters, which work along the substrate concentration gradient. To transport organic anions, including steroid conjugates, thyroid hormones, prostanoids, digoxin, statins, methotrexate, and antibiotics. OATP1B1, OATP1B2, OATP2B1, OATP3A1, and OATP4A1 are expressed in the human placenta [88–91]. OATP2B1 is abundantly expressed in the placenta and localized in the basolateral membrane of the syncytium [88] and OATP1B3 is located on the apical surface of syncytiotrophoblasts [90].

Repaglinide, a known OATP substrate was used in the *ex vivo* placental perfusion model to evaluate the placental transfer of this drug. Using antipyrine as a reference for passive diffusion, it was observed that the rate of repaglinide transport from the mother to the fetus was low, while this was higher in the fetal-to-maternal direction. This highlighted the importance of active transport by the OATP transporters in fetal exposure to repaglinide [92]. OATPs play a role in bile acid and bilirubin efflux from fetal hepatocytes toward the fetal blood and from the trophoblast to the maternal blood, facilitating the transfer of these potential toxins from the fetus to the maternal circulation [87]. The bile acid transporter, OATP1A2, is localized to the vasculosyncytial membrane and apical surface of syncytiotrophoblasts and OATP1B3, to the vasculosyncytial membrane of the syncytiotrophoblasts. In intrahepatic cholestasis occurring during pregnancy, the expression of both transporters is significantly reduced, relative to the normal placenta [93].

24.3.1.2.2 OAT. OATs are involved in the elimination of a variety of endogenous substances, xenobiotics, and their metabolites from the body and have weak structural similarity to the OCTs. The endogenous substrates of OATs are cyclic nucleotides, prostaglandins, urate, dicarboxylates, and so on, while exogenous substrates are anionic drugs and environmental substances. Most OATs are expressed in the kidney and some are expressed in the liver, brain, and placenta. These transporters are involved in renal secretory pathways for organic anions and in the distribution of organic anions throughout the body. OATs expressed in the human placenta were OAT1/SLC22A6, OAT3/SLC22A8, and OAT4/SLC22A11. OAT1 and 3 are present in syncytial basement membrane and involved in the elimination of toxins and xenobiotics from the fetal circulation, whereas OAT4 is expressed in the cytotrophoblast layer that underlies the syncytium [52].

24.3.1.2.3 OCT. OCTs expressed in human placenta are OCT1, OCT2, OCT3 (SLC22A3), OCTN1 (SLC22A4), and OCTN2 (SLC22A5). OCT1–3 are high capacity nonneuronal monoamine transporters. Their substrates include amiloride and cimetidine. The OCT inhibitor quinidine is reported to inhibit acetylcholine release in human placental tissue [94]. OCTN1 is localized to the brush border membrane of the syncytiotrophoblasts of term placenta, and involved in transport of fluoxetine, citalopram, and verapamil [52]. OCTN2 is a high affinity L-carnitine uptake protein localized on the apical surface of syncytiotrophoblasts of the placenta. It has been reported to be involved in the transport of L-carnitine across the placenta, which is

inhibited by levamisole and progesterone in human trophoblast cells. The transporter is additionally involved in the movement of methamphetamine, quinidine, verapamil, cephaloridine, glibenclamide, and imipramine. Thus, it plays an important role, as some of these drugs have been shown to be toxic for the fetus [52,94].

24.3.1.2.4 Other SLC Transporters. Other SLC transporters expressed in placenta are monoamine transporter (SLC6A), nucleoside transporter (SLC29A), and carboxylate transporter (SLC16). SLC6A transporters that are involved in the transport of serotonin and dopamine are named *serotonin transporters* (SERT/SLC6A4) and *dopamine transporters* (NET/SLC6A2), respectively. They are involved in the transport of amphetamines and cocaine, respectively. SLC29A is located on the brush border membrane of the syncytium and transports purine and pyrimidine across the placenta. It was also found to be involved in the transport of chemotherapeutics, nucleoside analogs, and vasodilator drugs such as dipyridamole and dilazep. SLC16 is an H⁺ cotransporter that is involved in the movement of carboxylates across the syncytium [52].

24.3.2 Transporters in the Fetus

There are relatively limited drug-transporter-based studies on the human fetus. PgP is the most studied transporter, and its distribution in the fetus is represented in Fig. 24.2. Highest expression is in the cardiac muscles and the kidney tubules during the gestation period. It is not expressed in the pneumocyte and bronchiole of the lungs, but the expression is higher in the bronchi during 18 to 20 weeks' gestation. In the adrenal gland, PgP is expressed only in the definitive cortex zone and no expression is reported in the fetal zone and medulla of the adrenal gland [95]. The early fetal brain has low expression of microvessel PgP, rendering the fetus more susceptible to the toxins in maternal circulation. With advancement of pregnancy, there is a significant increase in PgP expression in the fetus and is likely the reason for the observed higher responsiveness of PgP function in primary brain endothelial cells to glucocorticoids [95]. Synthetic glucocorticoids administered to pregnant women at risk of preterm delivery were found to increase the protective capacity of the developing fetal blood–brain barrier, depending on the time of exposure [96]. Immunohistochemical staining was used to visualize the expression and localization of PgP in the developing human fetus during cerebral cortex formation [97]. At 12 weeks of gestation, PgP was diffusely located in the endothelial cells lining the primary cortex microvessels. At 18 weeks, PgP was present in the cortex and subcortical vessels, and at 22 weeks, it was concentrated in the endothelial cell membranes. Radial glial cells and astrocytes did not stain for PgP in any of the samples. There was low expression of PgP in the radial glia at 18 weeks' gestation and at midgestation, where it was observed in the abluminal endothelial cell membrane. These studies demonstrate that PgP is expressed early during human cerebrocortical microvessel development and at midgestation, where its efflux activity is regulated by interactions with the caveolar endothelial cell compartment [97].

MRP1 and BCRP are also expressed in the developing human central nervous system (CNS). While MRP1 is expressed in choroid plexus and ependymal cells, BCRP is most prominently expressed in microvessel endothelial cells of the CNS. Both PgP and MRP1 are also found in large pyramidal neurons. Immunostaining during

Figure 24.2 Pictorial representation showing distribution of PgP transporter in placenta and organs of the fetus. (See color insert.)

different stages of gestation showed increase in PgP expression during gestational maturation, whereas MRP1 and BCRP expression remained constant [98]. In embryonic and fetal membranes, BCRP expression helped to ensure proper function of the fetoplacental unit [99].

BSEP, MRP2, and MDR3 are the major hepatic canalicular transporters, mediating bile secretion in the fetus [100]. Human liver samples from the fetus at 14–20 weeks of gestational age and adults were tested for mRNA expression of BSEP, MDR3, MRP2, Na⁺-taurocholate cotransporting polypeptide (NTCP), and farnesoid X receptor (FXR) genes. Immunohistochemical staining of BSEP, MDR3, and MRP2 was performed on the fetal and adult livers. All genes tested were expressed at midgestational age. MDR3 and NTCP showed significantly lower levels in fetal liver as compared to the adult. Immunohistochemical staining of MRP2 in the fetal liver was canalicular, BSEP was both intracellular and canalicular, and there was low expression of MDR3, which was found only occasionally along the canaliculi.

In a mouse model, Ntcp and Bsep were the key transporters for hepatic bile acid uptake and excretion. Ntcp and Bsep mRNA levels in the liver were low in the fetus and reached the highest levels at parturition. After birth, mouse Ntcp and Bsep mRNA levels decreased to less than half, before gradually increasing to adult levels by day 30 [101].

24.4 DRUG-METABOLIZING ENZYMES (DMEs)

Owing to changes in the sex hormones progesterone and estrogen in different trimesters of pregnancy, alterations occur in the expression and activity of DMEs in the mother, particularly in the placenta [14,102–106]. Some of the DMEs are typically absent in the fetus and develop either immediately or subsequently after birth.

24.4.1 DME Changes in the Pregnant Mother

The sex hormones are ligands of pregnane X receptor (PXR) and thus significantly influence the expression of CYPs. For example, levels of CYP2A6, CYP2C9, CYP2D6, and CYP3A4 were increased, while expression of CYP1A2 and CYP2C19 was lowered during pregnancy [107]. Also, expression of UGT1A4 and UGT2B7 was enhanced. Such changes in DME expression have the potential to alter the pharmacokinetics of drugs and even carry the propensity to form toxic metabolites, with the possibility to even cause birth defects. For example, a genetic defect in arene oxide detoxification increased the risk of birth defects in case of an epileptic mother who has been treated with phenytoin [108]. A study to assess potential contribution of enzymatic bioactivation of phenytoin to a teratogenic metabolite, using a murine embryo culture model, suggested that the embryo had expression of responsible DMEs [109]. Similarly, a direct relationship between pharmacogenetics and drug-induced birth defects has been proposed for folate metabolism [110]. It has been suggested that enhanced metabolic conversion of valproate to its toxic metabolites (e.g., 2-propyl-4-pentenoic acid) during pregnancy is associated with its teratogenicity at higher doses [111].

24.4.1.1 CYP450. Endogenous sex hormones, namely, progesterone and estrogen, and exogenous substances, such as rifampicin, phenobarbital, and polyaromatic hydrocarbons (PAHs), influence expression and activity of CYPs via influence on nuclear

receptors and/or immunomodulators [112]. Hepatic transcription factors such as aryl hydrocarbon receptor (AhR), PXR, and constitutive androstane receptor (CAR) play a critical role in the upregulation of the expression of hepatic CYPs [113].

Among the CYPs, CYP1A2 activity reduces gradually from early to late pregnancy [107]. The respective reduction was as much as 33%, 48%, and 65% during 14–18, 24–28, and 36–40 weeks of pregnancy relative to the postpartum period [114]. A typical example of the influence of lowering in activity of this enzyme is the decrease in clearance of caffeine that becomes half in the second and third trimesters, with no change during first trimester or after delivery [9]. Similarly, CYP2C9-mediated metabolism increased during pregnancy in humans, while CYP2C19-dependent metabolism was decreased. The clearance of phenytoin, a CYP2C9 substrate, was increased during pregnancy [115], and the dosage of the drug was required to be increased by 85% to maintain therapeutic plasma concentration [116]. In contrast, CYP2C19-mediated metabolism of proguanil to its active metabolite (cycloguanil) decreased during the pregnancy. The proguanil to cycloguanil plasma concentration ratio increased by 63% during second and third trimesters of pregnancy, as compared to postpartum [117]. In a rat study, *cyp2c6* and *cyp2c12* transcription and protein expression were not significantly changed during pregnancy, although intrinsic clearance of *cyp2c6*-mediated diclofenac 4'-hydroxylation was increased twofold on day 19 of gestation, when compared to nonpregnant controls. This was explained through the decrease in K_m for 4'-hydroxydiclofenac formation [118].

The expression of CYP2D6 is predominantly under the genetic control, and thus far, no chemical inducers of this enzyme have been reported. The enzyme's activity fluctuated from preovulatory to luteal phases and subsequently during different terms of pregnancy. CYP2D6 activity was found to be 25% lower during luteal phase, as compared to the preovulatory phase. This was attributed to fluctuations in the progesterone levels [119,120]. This steroid has also been implicated in increased CYP2D6 activity, which goes up by 26%, 35%, and 48% at 14–18, 24–28, and 36–40 weeks of pregnancy, respectively [114]. CYP2D6 mRNA is reported in the fetal liver and term placenta, while protein expression was not found [114,121–125]. In other reports, two classical CYP2D6 probe substrate drugs, dextromethorphan and metoprolol, were used to assess the enzyme's activity. Data showed significant increase in CYP2D6 activity [121,126]. At 26–30 weeks of gestation, metoprolol oral clearance was increased sixfold and its bioavailability decreased to half as compared to postpartum [126]. A significant decrease in the urinary dextromethorphan/dextrorphan metabolic ratio, indicative of an increase in CYP2D6 activity, was also observed during all trimesters of pregnancy [114]. In another study, 53% decrease and 63% increase in the dextromethorphan to dextrorphan plasma concentration ratio was found in extensive metabolizers and poor metabolizers of pregnant mothers, respectively [121].

The expression of CYP2E1 has been shown to be suppressed, particularly during late pregnancy [127]. Koh *et al.* [128] correlated CYP2E1 expression in mouse livers with that of peroxisome proliferator-activated receptor α (PPAR- α). The authors observed potential involvement of PPAR- α in the downregulation of CYP2E1 during pregnancy. CYP2E1 induction/suppression profile in pregnant females who consume alcohol has been correlated with congenital abnormalities including low birth weight, mandibular hyperplasia, and developmental delay [129]. In the rodents, *cyp2e1* expression has been demonstrated to be controlled at three different levels: posttranslationally by

ligand-dependent enzyme stabilization, translationally by stabilization of its RNA, and transcriptionally during ontogenesis [130].

CYP3A4 and CYP3A7 are the major isoforms expressed in adult and fetal livers, respectively. Unadkat *et al.* [113,131–136] studied changes in pharmacokinetics of CYP3A4 substrates (anti-HIV drugs) during pregnancy in different species, including humans, and suggested that decrease in $C_{\max}$ of anti-HIV drugs during pregnancy was due to increase in CYP3A4 expression. On the other hand, the expression of CYP3A7 was downregulated during intrauterine development in the first trimester of pregnancy [137].

24.4.1.2 Uridine 5'-Diphosphoglucuronosyltransferase (UGT). UGT is a phase II enzyme that consists of two major families, UGT1 and UGT2. UGT expression is significantly influenced by changes in female sex hormone levels and by activation of nuclear receptors [14,102]. UGT1A is expressed in the first trimester but not in the term human placenta [138,139]. UGT1A1 is involved in the glucuronidation of bilirubin. During pregnancy, its activity is enhanced by progesterone in a concentration-dependent manner, whereas estrogens have no influence [14]. UGT2B isozyme expression is not influenced by changes in progesterone and estrogen during pregnancy [14].

24.4.1.3 Glutathione S-Transferase (GST). GSTs play a central role in xenobiotic detoxification and have been classified as GST-alpha (GSTA), GST-mu (GSTM), GST-pi (GSTP), and GST-theta (GSTT) subtypes. These enzymes neutralize electrophilic metabolites by conjugating them with glutathione. Overall hepatic GST activity was induced during pregnancy [140].

24.4.1.4 Sulfotransferase (SULT). Sulfation is an important mechanism for regulating biological activity of numerous hormones and neurotransmitters. Tissue-specific regulation of SULT expression was observed during placental development. SULT activity assays and Western blot analysis in human placental cotyledon and membranes (amnion, chorion, and decidua basalis) from 13 to 42 weeks of gestation revealed expression of phenol and catecholamine sulfotransferases at the highest levels. These were generally higher in the villous than membranous tissues [141]. Estrogen sulfotransferase existed at extremely low levels during early pregnancy and gradually increased through midgestation and late gestation in the decidual component of the placenta [141].

24.4.2 Changes in DMEs in the Placenta

The placenta undergoes changes during different stages of gestation and this contributes to a high degree of variability in enzymatic activities and biochemical components. In the human placenta, many changes occur during the course of gestation periods, with variability contributed by factors, such as diet and exposure to environmental chemicals. However, biochemical processes related to the drug metabolism are not extensively studied in placental tissues, as compared to the liver. This is likely due to the strong association between the hemoglobin/methemoglobin and the homogenized placental membranes, which contributes to difficulty in the preparation of placental DMEs [142–144].

The enzymes CYP1A1, CYP1A2, CYP2C, CYP2D6, CYP2E1, CYP2F1, CYP3A4, CYP3A5, and CYP3A7 are expressed at mRNA levels in the first-trimester placenta. CYPs reported in full-term placenta are CYP1A1, CYP2E1, CYP2F1, CYP3A3/4, CYP3A5, and CYP3A7. The expression of these enzymes in placenta was much lower than that in the liver and lungs. The methodologies used for the detection of CYPs in human placenta in the first-trimester and full-term placenta are listed in Table 24.4.

The subtype CYP1A1 was expressed during both first trimester and full term, which was reflected by ethoxyresorufin-O-deethylase (EROD) activity in the human placenta. The enzyme was involved in the metabolism of xenobiotics that are widely used in pharmacotherapy or even present in the diet. It also played a key role in the metabolic activation of procarcinogens, such as arylamines and PAHs, that form adducts with placental and fetal DNA. CYP1A1 expression was transcriptionally upregulated through ligand-activated AhR, which plays an important role in adaptive response to xenobiotics. AhR was activated in the placenta by maternal cigarette smoking, polychlorinated biphenyls and dichlorodiphenyltrichloroethane (DDT) [150–152]. The toxicological consequences of CYP1A1 induction in the placenta of women smokers, have been summarized, which include premature birth, intrauterine growth retardation (IUGR), structural abnormalities, fetal death or placental abruption, risk of low birth weight, low birth length, and low head circumference [153]. The expression of the subtype CYP1A2 is reported in the first-trimester placenta, while it was absent in full-term placenta [123]. Similarly, CYP2C and CYP2D6 showed mRNA expression in first-trimester placenta, while protein expression was not detected at any stage of pregnancy [154].

CYP2E1 was detected at mRNA level in the placenta but was not detected immunohistochemically and by enzyme activity assays. This could be due to lower sensitivity of the assays or there is the possibility that mRNA might not have translated into active protein as both posttranscriptional and posttranslational mechanisms regulated its expression [155]. Placental CYP2E1 was induced on heavy alcohol consumption and is held responsible for susceptibility to alcohol-related birth defects. The proposed reason is the increase in the amount of circulating placental acetaldehyde [156,157]. The expression of CYP2F1 mRNA was established in both first-trimester and full-term placenta using RT-PCR, but protein expression and function values are yet not proven [154].

CYP3A isoforms were expressed in the placental trophoblast cell lines [158]. Although the activity of CYP3A *per se* was not found in the human placenta, the expression of CYP3A4/5 was found in the full-term placenta [123]. In comparison, CYP3A7 was detected in the first- and second-trimester placentas, while it was absent in full-term placenta [159].

24.4.3 Changes in DMEs in the Fetus

A study to assess the effect of smoking and genetic polymorphisms on the fetus in 293 women in Japan revealed that birth weight and length were significantly lower in infants born to heavy smokers with the wild-type *AhR* and the *CYP1A1* variant genotypes (m1/m2 + m2/m2) or the *GSTM1* null genotype [160]. CYP1A2 has been reported to be absent in the human fetal liver, appears gradually after birth, and takes several months to years to reach the adult levels [161]. Another important subtype is CYP2D6. Its mRNA is reported in the fetal liver but no protein expression was found [114,121–125]. The concentration of CYP2D6 is shown to increase a few days after birth [125], but remains low during the first month of life (about 20% of an adult's levels) [162]. Its level in

TABLE 24.4 The Presence of CYPs in Human Placenta during Different Gestational Stages and Methodologies Used for their Detection

CYP	First-Trimester Placenta	Methodology Used for Detection	Full-Term Placenta	Methodology Used for Detection	Metabolic Role
CYP1A1	+	Enzymatic activity determinations [139], immunoblot methods [124], RT-PCR [145], Western blot, slot-blot analyses [146]	+	Enzymatic activity determinations [123], mRNA in northern blot, RT-PCR [123], immunohistochemistry, immunoinhibition assays [123]	Detoxification of aromatic hydrocarbons 146,147
CYP1A2	+	RT-PCR	—	RT-PCR, diagnostic inhibitors [123]	Detoxification of aromatic amines [148]
CYP1B1	+	RT-PCR	+	RT-PCR [123]	Low molecular weight procarcinogens (nitrosamines), organic solvents, and drugs such as paracetamol and chlorzoxazone [149]
CYP2C	+	RT-PCR [124]	—	RT-PCR [123]	
CYP2D6	+	RT-PCR [124]	—	RT-PCR [123]	
CYP2E1	+	RT-PCR [124]	+	RT-PCR [123], western blot	
CYP2F1	+	RT-PCR [124]	+	RT-PCR [123]	
CYP3A4/7	+	RT-PCR, immunoblot methods [123], Western blot,	+	Northern blot, RT-PCR [123], Western blot	

Abbreviations: RT-PCR, reverse transcription polymerase chain reaction.

newborn is low even during lactation, and the same is independent of the functional genotype. Thus, fetuses and neonates have been categorized as poor metabolizers of CYP2D6 substrates (such as dextromethorphan), as the clearance of the latter is low. Therefore, individualization of dosing has been suggested in order to prevent drug accumulation or toxicity of CYP2D6 substrates [163]. The variability of CYP2D6 activities in infants older than 1–2 weeks is found to be similar to the adults, and is also influenced by the genotype [164].

On the other hand, CYP2E1 is not detected in the fetal liver but was expressed in the first few hours following birth, and the same was independent of the gestational age (between 25 and 40 weeks). The steady increase in expression continued during the first year [130]. Similarly, CYP3A4 expression level was initially very low (10 pmol/mg protein), which increased with age [137]. Against it, the expression of CYP3A7 in fetal liver microsomes falls between 311 and 158 pmol/mg protein and showed significant expression till six months of postnatal age [165].

In a report on UGTs [166], UGT1A1 was found to be absent in the prenat and its expression was triggered during birth. It reached adult levels by three to six months of postnatal age. UGT1A3 expression was observed in the fetus and neonate liver, which was one-third of the adult expression. The same conclusion is drawn in other studies where UGT1A subfamily members were found to be absent in the fetus, their expression appeared in neonates and gradually reached adult levels at 10 years of age [167,168]. UGT2B7 is the only UGT2B isoform observed in the liver of fetus aged 15–27 weeks, where its expression was 10–20% of the adults. These levels remained consistent till birth, after which there was a rapid increase in expression that reached adult levels by two to six months of age [169,170].

Expression of GSTs has been found to vary to a large extent during fetal growth. At gestational age of 10 weeks, expression of hepatic GSTA1 and GSTA2 was to the extent of 182.4–247.2 and 14.2–31.2 pmol/mg cytosolic protein, respectively. During the initial two years, the levels of GSTA1 and GSTA2 increased by 1.5- and 4-folds, respectively. Thereafter, they were detected in the liver throughout life. Like GSTA, the GSTM subtype also exhibited very low expression during early stages of life and the expression increased fivefold by adulthood. GSTP1 was detected at the level of 18.0–25.2 pmol/mg cytosol proteins during 10–22 weeks of gestational age and decreased continuously in the subsequent trimester. The expression is not reported in the adult liver. The pattern of fetal kidney expression of GSTP1 before 35 weeks' gestational age was similar to that observed for GSTA1/A2. After 35 weeks of gestation till term, the same was restricted to the collecting tubules and the distal loop of Henle [171–173]. The presence of GST isoforms in the urinary epithelia, digestive tract, and respiratory tract highlighted the importance of GST in detoxification reactions at a very early age, suggesting that an embryo has the capability to defend against toxic compounds to some extent [163].

No activity of SULT1A3 has been reported in adult human liver, although it is expressed at high levels early in the fetal development [174]. The same decreased significantly in the late fetal and early neonatal development. The fetal lung had significant SULT1A3 activity, while neonatal levels were considerably lower. The expression of SULTs in the developing fetus is more widespread than that in the adult. Studies on enzyme activity and protein and mRNA expression of SULT1A, SULT1B, SULT1C, SULT1E, and SULT2A families in a variety of human fetal and adult tissues revealed that SULTs were expressed in the human fetus at levels equivalent to or higher than

the adults [175]. SULT1B1 was expressed at high levels in the fetal small intestine, while SULT1C2 was expressed in fetal liver, kidneys, and small intestine but not in the adult liver or colon [175].

24.5 CLINICAL IMPLICATIONS OF DRUG THERAPY DURING PREGNANCY

As discussed above, pregnancy results in physiological changes, development of the placenta and changes related to the development and protection of the fetus. The placenta plays a significant role in drug metabolism and transport of xenobiotics between maternal and fetal compartments. Apart from genetic factors and maternal infections, it is the unwanted transfer of drugs from the mother to the fetus that can affect the latter through different stages of its growth and lead to drug-related birth defects and teratogenicity. Drugs influence the development of the fetus at three stages of pregnancy: (i) fertilization and implantation (from conception to 17 days), leading to the failure of pregnancy, which is generally unnoticed; (ii) organogenesis (18–55 days), wherein deformities in organs can occur; and (iii) growth and development (56 days onwards), where the end result is developmental and functional abnormalities. Toxicity of some drugs depends on the stage at which these are administered.

Numerous drugs prescribed to pregnant women, such as antihypertensives, antiepileptics, anticancer drugs, and anti-inflammatory agents, have the potential to cause birth defects in the fetus after crossing the placenta. Drug-related birth defects are heart malformations, including holes in the heart chambers; premature birth; persistent pulmonary hypertension of the newborn; brain defects; facial and spinal defects and fetal alcohol syndrome. Table 24.5 summarizes the examples of drugs that can cause teratogenic abnormalities.

24.6 CONCLUSIONS

Pregnancy presents additional challenges for safe and efficacious drug administration to the prospective mother. The physiological changes in the body as a whole, modifications in the drug transporters, alterations in expression of DMEs, and the presence of polymorphic forms make the prediction of pharmacokinetics and pharmacodynamics of any given medication difficult. Added are the ethical concerns with respect to the safety of the fetus, so hurdles exist in testing and following the paths taken by drugs in pregnant women. This is the reason for the relatively limited research in the field. There is a need for improvement in preclinical models for evaluating the contribution of DMEs and transporters early in the drug development. This may help to design and develop safer drugs, with reduced fetal exposure.

ACKNOWLEDGMENT

The authors wish to thank Deepak Suresh Ahire and Ninad Ramesh Varkhede (NIPER, SAS Nagar) for their help in the literature search and compilation of data.

TABLE 24.5 Drugs Administered to Pregnant Mothers (under Various Disease Conditions) during Different Trimesters and Their Teratogenic Effect on Fetuses

Drugs Crossing Placenta	Trimester	Fetal Birth Defect and Toxicity	References
Selective serotonin uptake inhibitors	First trimester	Omphalocele, craniosynostosis, congenital heart defects, laterality defects, conotruncal defects, atrioventricular defects, right ventricular outflow tract obstruction defects, left ventricular outflow tract obstruction defects, septal defects, anomalous pulmonary venous return.	176,177
Female sex hormones	First trimester (taken unknowingly)	Cardiovascular birth defects	178
Lamotrigine	First trimester	Orofacial cleft, ventricular septal defect, bilateral hip dislocation, club feet	179
Folic acid antagonists	Second and third months	Cardiovascular defect	180
Bendectin	First trimester	Isolated cleft palate, cleft lip with or without cleft palate, heart defects	181
Tumor necrosis factor antagonists	NS	Vertebral abnormalities, anal atresia, cardiac defect, tracheoesophageal, renal, and limb abnormalities association	182
Tranquilizers (meprobamate or chlorthalidone)	First 42 d	Teratogenic	183
Cocaine	NS	Embryonic or fetal vascular disruption	184
Aspirin	First trimester	Teratogenic	185
Methamphetamine	First and second trimesters	Teratogenic	186
Acetaminophen	First trimester	Gastroschisis	187
Trimethadione	NS	Malformed ears, cleft palate, cardiac defects, urogenital malformations, and skeletal abnormalities	188
Carbamazepine	NS	Spina bifida	189

Abbreviation: NS, not specified.

1.1 SUMMARY

The oral delivery of small drug molecules is still the favored target of most drug discovery programs. Medicinal chemistry practices are skilled in the introduction of potency and selectivity against a desired target; however, an oral drug has to combine solubility and permeability, and rates of elimination low enough to sustain therapeutic concentrations. To achieve this screening cascades need to be introduced to select molecules with the right pharmacokinetic properties and to guide structure–activity relationships (SAR). Although there appears considerable freedom to target the right properties, many of the pharmacokinetic properties are dictated by the characteristics of the target and its active/binding site. Open solvent exposed binding sites often lead to larger drug molecules with high polar surface areas (PSAs), whereas smaller hydrophilic pockets lead to smaller molecules with lower PSA. This dictates the intrinsic permeability of a molecule that determines the fate of its overall disposition. Highly permeable molecules are usually cleared exclusively by metabolism, whereas complex

processes involving metabolism and transporters clear less permeable molecules. With these molecules it is difficult to unravel the rate-limiting step.

Designing the screening cascade correctly is vital since information may not be helpful or may be misleading at the wrong stage. Moreover, even the basic absorption, distributions, metabolism and toxicity (ADMET) screens for solubility, permeability, and metabolic vulnerability can give results compromised by factors such as cosolvents (DMSO), the presence of transporters or membrane binding. Other systems, such as induction screening, may not provide information that can be put into context until the potency and likely dose of the candidate molecules can be estimated. As such these screens probably should be confined to the final phases of the discovery program. For instance, plasma protein binding information is only valuable to determine free fraction in *in vivo* experiments and thereby calculate unbound drug concentrations. Unbound drug concentrations allow understanding of the relationship between *in vitro* pharmacology measurements and *in vivo* activity. They also allow calculation of intrinsic clearance, which relates directly to *in vitro* clearance experiments such as microsomal metabolism rate. Protein binding does not determine *in vivo* unbound drug concentration, which is determined by intrinsic clearance. Attempts to modify drug series to reduce protein binding to achieve better efficacy are scientifically incorrect and may lead discovery programs down false alleys.

1.2 INTRODUCTION: THE STAGES OF DRUG DISCOVERY

Around 90% of newly approved drugs are small molecules. Within small molecules the oral route is the most favored with nearly 90% of drugs administered this way. Other routes include intravenous (5%) inhaled and transdermal. The oral route is considered the optimum for small molecule delivery as it allows a wide range of doses to be administered, allows convenient patient self-administration, is adaptable to varying dosage regimens, allows convenient pack size and needs no special equipment. To provide an oral drug the molecule must undergo dissolution in the gastrointestinal tract (GIT), absorption across the GIT, and penetration to the target, if it is intracellular or in the central nervous system (CNS). Moreover, the drug has to be present in the circulation and body for sufficient time and at concentration which activate or inhibit the pharmacological target, to provide a convenient dosage interval.

Whether we will see a change to new modalities in the next decade, in 2010 drug discovery and development programs were still mainly directed toward oral drugs. The methods used to discover drugs have gradually changed to what can be termed *strictly rationale led*. In these programs, a drug is developed against a known target, and usually the drug is optimized to only have affinity and selectivity toward this target. Many technologies including genomics, molecular biology methods of protein expression, microplate high throughput screening technology (HTS), X-ray crystallography have helped facilitate this direction.

A simple scheme for the stages of drug discovery and development is illustrated below:

Stage I: Target Identification. The protein of interest becomes apparent in the disease process. The identification may be triggered by genomics and proteomics. For instance, a group may be particularly resistant or sensitive to a disease and share a common genetic mutation, or a protein may be consistently overexpressed

or lacking in a disease. Both clearly are connected but the technology used for identification varies. Validation of the target is also important not only in terms of efficacy, but also safety. This will be discussed in more detail in Section 1.6.1.

Stage II: Series/lead identification comprising HTS leading to groups of compounds often termed *HITS*. These are compounds active in the HTS screen but need to be validated in terms of more rigorous pharmacology, structural inspection, purity, and so on. Some of the *HITS* may be deemed leads and trigger a chemical series. Although used in different ways, the term lead and lead series usually describes the compounds validated from *HITS* and seen as having sufficient chemical attractiveness to be predicted as capable of being modified into a potential drug. Lead series may also be assembled from fragment-based approaches (which assemble the lead from fragments shown to interact with the target) followed by chemistry follow up in literally joining these molecules together. This approach uses early examination of the modes and forms of interaction of the molecule with the target such as X-ray crystallography.

Stage III: Compound identification comprising series/lead development generating SAR, leading to compounds with most of the desirable properties. This is the time-consuming process of turning a potential lead, which may have low affinity for the target, low selectivity against some other proteins, and pharmacokinetic issues such as high metabolic instability. The process culminates in the production or nomination of a development candidate (and back up selection). Often, all the problems identified in the lead series are not completely resolved, and most drug candidates and even drugs are a compromise rather than a “perfect candidate.”

Stage IV: Candidate Development. The drug candidate is profiled in human volunteers (phase 1) for tolerance and pharmacokinetics (adequate oral drug properties to activate/inhibit the pharmacological target with an acceptable dosage regimen). The drug is then administered in increasing numbers (phases 2 and 3) to patients to demonstrate safety and efficacy. Each stage is supported by preclinical toxicology, pharmacy (formulations), and so on.

Following Stage III, the properties of a molecule are fixed, and while ADMET work is an essential part of drug development, it cannot improve the intrinsic properties of a molecule. It does of course optimize the use of the drug in patients in terms of efficacy and side effects. Dosage regimens can be optimized for patients particularly where comeds are likely to be administered and ADMET preclinical work in combination with clinical pharmacokinetic studies is pivotal.

The statement concerning most drugs being a compromise is largely due to two factors.

1. Humans (and animals) have evolved to have multiple defense mechanisms against foreign molecules. Like many biological systems, there is considerable overlap and compensation. Moreover, these systems are usually promiscuous and able to accept a wide range of chemical forms and structures.
2. The drug targets chosen dictate to a considerable degree the nature of the chemical matter that interacts with them. Thus the medicinal chemist is constrained in his choices as to what molecules he can synthesize and what properties he wants in those molecules.

Even before a single molecule is synthesized or screened certain ADMET properties are therefore defined. The nature of the target largely determines the type of chemical matter and its complexity.

1.3 TARGET SPACE DEFINES THE BROAD PROPERTIES OF THE DRUG

Targets for drug discovery programs such as aminergic GPCRs, some ion channels, and certain enzymes such as cyclooxygenase and acetylcholinesterase have small cavity volumes (less than 1000 Å³ buried within the protein target) and a large hydrophobic surface (representing 30% or greater of the total area). Polar ionic interactions are restricted and confined to this buried active site. Lead series, development candidates and drugs against these targets are small with moderate or low PSA and lipophilicities. These properties are conducive to discovering oral drugs. Some targets (usually lipid or lipid acid enzymes and carriers) require high lipophilicities to interact with the target. For instance, cholesterol ester transfer protein was an attractive target based on initial genomic data. Cholesterol esters have extremely high lipophilicities and it is not surprising, therefore, that inhibitors of the protein are all of very high lipophilicity. The development of these compounds has been hampered by poor solubility, inadequate dissolution, and the need for complex formulations. For some the natural substrate is a protein a considerable portion of which interacts with the active site. Aspartyl proteases, the family of which includes HIV protease, rennin and β-secretase targets for AIDS, hypertension and Alzheimer's respectively, have open binding cavities of greater dimensions, a smaller proportional hydrophobic surface and the need for more polar ionic interactions. Lead series, development candidates and drugs against these targets are large (MW >500) with high PSAs and lipophilicities. The consequences of these properties are explained below.

1.4 ADMET SPACE LIMITS THE POSSIBILITIES OF SUCCESS FOR AN ORAL DRUG

Membrane permeability is pivotal to ADMET properties defining absorption, rapid equilibrium between tissues, cell interiors and the circulating unbound drug in plasma, and the route of drug clearance and elimination. Drugs of high membrane permeability are not cleared renally because of tubular absorption. Permeable drugs rapidly establish equilibrium across membranes. This means an absence of influence by active transport processes since the passive flux is faster than any active transport flux. Such drugs are normally cleared by metabolism, whether this is by default, or that the groupings and structure giving good permeability are also amenable to metabolism by enzymes such as CYP450s is an introduction into how metabolism may be attenuated but is unlikely to be abolished. The influence of permeability on clearance is shown in Table 1.1. Drugs with lower membrane permeability may have their disposition influenced by transporters, both efflux and influx. The rate of transport flux now is (much) greater than the intrinsic passive flux so these molecules move in a largely unidirectional way across membranes with the requisite transporters present. Efflux transporters (e.g., Pgp) are particularly important in the GIT and the blood brain barrier. These transporters also play a role in active renal excretion and biliary excretion. The effects in the GIT

TABLE 1.1 Classification of the Disposition Fate of a Compound Based on Its Permeability Across a Biological Membrane

Permeability	Low	Medium	High
PSA/Log <i>P</i> Absorption	High Low (e.g., aliskeran) unless MW is less than 250 Da and absorbed by paracellular route (e.g., atenolol)	Medium Variable Influenced by permeability and transporters (e.g., nelfinavir)	Low High via transcellular route (e.g., propranolol)
Bioavailability	As for absorption	As for absorption and metabolism	Variable. Influenced by metabolism
Clearance	Renal or biliary (possible transporter involvement)	Transporters and metabolism	Metabolism

Permeability of a biomembrane is favored by lipophilicity and attenuated by polar functionality (PSA). Cells have tight junctions, which act as pores. The pore size is large in most capillaries allowing polar drugs access to extracellular receptors such as GPCRs. Pores are small in the capillaries of the blood brain barrier and moderate in the gastrointestinal tract.

are somewhat attenuated by the effects of saturation of the transporter by the high concentrations of drug present after the dissolution process. Most calculations suggest that the volume of gastrointestinal fluid in the small intestine is around 250 mL in which the entire administered dose can dissolve. In contrast, saturation of those present in the blood brain barrier is unlikely to occur at normal efficacious concentrations. Thus, drugs of lower membrane permeability may have reasonable oral absorption and bioavailability but not penetrate the CNS to a marked degree.

Membrane permeability depends on the drug being able to cross the lipoidal core of the membrane and is dependant therefore on the drug having affinity for lipid (lipophilicity). Lipophilicity (log *P* or log *D*) can be measured or calculated and can be conceived as being composed of two components that of molecular weight and polar surface area (PSA). Transfer through a membrane involves the complete removal of the molecule from water. Lipophilic groups have a positive solvation free energy and are readily soluble in the hydrocarbon core of a membrane. In contrast, the desolvation of polar groups is unfavorable and the groupings do not readily dissolve or penetrate the hydrocarbon core of the membrane. PSA is recognized as one of the most important measurements incorporating both structure and the ability of a molecule to form hydrogen bonds with solvent. A cutoff value for poorly permeable and (therefore, poorly orally absorbed) compounds has been set at >140–150 Å². Expressing the above concept as a virtual formula log *P* equates to molecular weight—PSA. This virtual formula defines ADMET space as a conceptual boundary that encloses the properties most likely to be associated with successful drugs. The dimensions of such a space are illustrated in Fig. 1.1. The formula explains the interconnectivity of the physicochemical properties. If we consider absorption, lipophilicity will always give high permeability across the membranes but, at its upper limits, solubility is so low that adequate dissolution is not achieved at clinical doses. The interconnection with molecular weight has spawned a belief that this characteristic is important per se.

Figure 1.1 Structures of I the initial HIT/lead compound in the CCR5 project leading to the discovery of maraviroc and illustrating the unhindered pyridine nitrogen leading to potent CYP450 inhibition and its replacement with benzimidazole II. The other structural changes produced a compound antivirally *active in vitro*. Changes to decrease lipophilicity used the triazole group and resulted eventually in maraviroc III.

Most likely, it is the fact that drug molecules are made from carbon (lipophilicity), oxygen, and nitrogen (PSA) and that as molecular weight approaches 500, the chances of too high a lipophilicity or too great a PSA increase so that a molecule does not dissolve in the aqueous media of the GIT or the molecule has low permeability to membranes.

When a lead is being advanced it is usual for the lipophilicity of the newly synthesized analogs to show an increase in lipophilicity particularly as the medicinal chemist tries to increase the potency of a molecule to low nanomolar from often low micromolar. The loss of solvent is a major contributor to the binding free energy. Lipophilic groups have a positive solvation free energy; this, together with favorable direct van der Waals interactions, make lipophilic interactions a key force in drug binding. In contrast, the desolvation of polar groups is unfavorable even though hydrogen bonds between the substrate and enzyme or receptor, are favorable. Overall, the contribution of polar contacts to the binding free energy, is likely to be variable owing to the balance of desolvation and actual binding. Lipophilic groups often, therefore, guarantee potency increases usually to the extent of 0.7 kcal/mol and compounds become increasingly lipophilic to achieve drug like (low nanomolar) potencies.

1.5 PROPERTIES NEEDED IN AN ORAL DRUG

1.5.1 Solubility

Material in the early phases of drug discovery is amorphous. Moreover, most screening systems are run with the compound handling systems using DMSO stock solutions. Thus, the usual measurement is kinetic solubility in which a (DMSO) stock solution of compound is added to aqueous solvent and the solubility rapidly determined. This method has inaccuracies due to the presence of DMSO and the rapid nonequilibrium conditions [1]. Crystallizing a compound (by definition) produces a less soluble form rendering the kinetic solubility measurements redundant and possibly misleading. More accurate measures are provided by thermodynamic solubility, which refers to the measurement of solubility by addition of the solid material, to aqueous media under conditions of equilibrium and requiring a long incubation time [1]. Such solubility methods are not adaptable to high speed screening and material handling systems. The dilemma then is how useful early measurements of kinetic solubility are on the

amorphous material and how timely are tedious thermodynamic measures of crystalline material. A final problem is the appearance of new polymorphs of the crystal, which can emerge anytime in the discovery, development, and even product cycle.

1.5.2 Permeability

During the discovery phase most screening systems rely on Caco-2 cells, MDCK cells, or artificial membranes. The cell lines provide a more realistic model of membrane systems, but usually have the assessment complicated by the presence of transporters systems. Thus the output is often not true passive flux (for poorly permeable compounds) but a composite of permeability and transport. The transporters are saturable rendering the choice of concentrations critical in making intercompound comparisons. It is noticeable also that interlaboratory variation is very high [2] making the data very difficult to apply across compounds sets from different laboratories.

1.5.3 Metabolic Stability

The rate of metabolism of compounds can be measured using liver microsomes, human hepatocytes, or recombinant enzymes. Microsomes offer a robust oxidative metabolism screen when fortified with NADPH regenerating systems. Consideration needs to be given to microsomal binding, particularly with lipophilic basic molecules and for comparative data a correction is needed for this [3]. Owing to the large variation in CYP450 enzyme content screening usually uses microsomes prepared from a pool (5–10 individuals) of livers.

Hepatocytes provide the full complement of oxidative and conjugation metabolism. Cryopreserved hepatocytes are normally utilized in compound screening, but caution should be exercised in comparing pathways as the freeze thawing process can lead to loss of cofactors. While microsomal binding is relatively easy to predict or measure, hepatocyte binding is much more difficult to estimate, and to scale, into an intrinsic clearance prediction.

Apart from obvious differences, in the metabolic pathways supported, microsomes and hepatocytes may give conflicting results for compounds of low cell permeability, where the rate of metabolism in microsomes is attenuated by the slow rate of flux across the hepatocyte cell membrane [4]. Much of the work supporting the use of *in vitro* systems such as microsomes to predict *in vivo* clearance used series largely populated with permeable compounds.

1.5.4 Drug–Drug Interactions

The effect of the emerging candidate drugs on existing concomitant therapy (drug–drug interactions, DDIs) can be examined by the use of fluorogenic substrates with recombinant enzymes, particularly CYP450s or human liver microsomes and selective substrates [5]. Often the screens are run in two phases with most compounds synthesized submitted to a high throughput screen using recombinant enzymes with relatively nonselective fluorescent probe substrates (the selectivity being gained by use of the individual isoforms). These screens tend to use a single substrate concentration (around 20–50 μM) and look for percentage of inhibition of the reaction against control. Incubations are conducted with and without preincubation

to look for competitive and time-dependent “mechanism-based” irreversible or quasi irreversible inhibitors. A second phase assay will often be used to examine compounds of high interest. This assay uses human liver microsomes and selective drug substrates. CYPs screened are generally 1A2, 2C9, 2C19, 2D6, 2E1, and 3A4. The selective substrates for these are universally recognized and are often phenacetin (1A2), diclofenac (2C9), *S*-mephenytoin (2C19), bufuralol (2D6), chlorzoxazone (2E1), and testosterone (3A4). These screens are now firmly established as selectivity screens.

1.5.5 Induction

Induction screening can use reporter gene assays, cultured human hepatocytes, tissue slices, or immortalized cells such as HepaRG [6,7]. Reporter gene assays offer the closest to a general screening system but may give false negatives due to the absence of interplay with other receptors involved in the induction process. This criticism also applies to cell lines. Hepatocytes, while a comprehensive system, are variable from donor to donor. The concern around induction varies greatly from company to company and is often related to intracompany experiences and choice of therapeutic area. Clinical induction is actually quite rare and is seen almost exclusively (not absolutely) with high dose drugs. The high doses of these drugs are necessary because of weak affinity for their primary pharmacology target (antiepileptics such as phenytoin and carbamazepine, 30–50 μM against their Na^+ channel target and around 10 μM against the PXR receptor mostly involved in CYP3A4 induction) or the need to maintain plasma concentrations above the IC^{90} (anti-infectives such as nonnucleoside reverse transferase inhibitors for HIV). The only compound identified with high potency is hepatorin (low nanomolar) which cannot really be termed *drug like*.

1.5.6 Plasma Protein Binding

Methods to determine protein binding and free drug largely rely on the separation of the unbound drug from the bound drug by dialysis, filtration, or centrifugation or a combination of these methods. During development, traditionally the drug was radiolabeled to make the assay simpler. The methods work well for moderately bound drugs but loose accuracy when drugs are more than 95% bound. Much of the accuracy concerns the variable nonspecific binding to the apparatus used. The accuracy was also confounded, traditionally, by the purity of radiolabeled compound available. Thus, many drugs are categorized as greater than 99% bound. This applies typically to acidic drugs such as nonsteroidal anti-inflammatory agents.

BIACORE SPR is a biosensor-based technique using surface plasmon resonance (SPR) technology and can be used to determine the kinetics of protein–ligand interactions including albumin and other plasma proteins [8]. This technique gives actual affinity data rather than just percentage unbound. From affinity the fraction unbound can of course be calculated. For instance, warfarin binds to albumin (c99% bound). Using BIACORE technology, it was shown that at high concentrations warfarin bound at more than one site on human serum albumin. The kinetics of the high affinity site were $K_d = 3.7 \pm 1.2 \mu M$ and a dissociation rate constant of $1.2 s^{-1}$. From the K_d value, binding of 99.4% was calculated.

1.6 HIERARCHICAL AND HORIZONTAL *IN VITRO* SCREENING SEQUENCES

Two process models of screening cover most approaches to drug discovery screening. The hierarchical model places the various screens in a sequence such that only compounds possessing certain criteria move to the next phase. For instance, a newly synthesized compound or series of compounds could be screened for target binding, close neighbors to target binding (selectivity), functional activity (particularly if an agonist), and then for solubility, permeability, metabolic stability, and DDIs. Appropriate compounds may be further progressed into *in vivo* screens for pharmacology and pharmacokinetics. In the hierarchical model, therefore, ADMET data is collected only on compounds with adequate potency and selectivity, and even the collection of this can be staged.

In the horizontal model, ADMET data is collected on all compounds synthesized in a single screening phase incorporating *in vitro* potency and selectivity and the suite of ADMET screens. The horizontal model may be considered optimum for looking for exceptions to druglike property rules and can build SAR streams rapidly so potentially allowing real time SAR of the type normally reserved for retrospective analysis.

These two models indicate a divergence of how the data is handled. The hierarchical model means that full data is available on a few compounds, can be manipulated on a spreadsheet and can be interpreted easily by a medicinal chemist. Certain screens can be moved up in priority as the project SAR reveal key flaws and problems. The horizontal model could result in more than 5000 data points to collate as SAR. This immediately requires computational systems and complex analysis to process and optimize. Moreover, the cost of providing this number of data points makes screening a very expensive process.

1.6.1 When are ADMET Properties Critical in Influencing Compound Progression

At any stage, ADMET arguments could be advanced for the progression or cancellation of a project. At target identification the structure of the protein, close family members, nature of the possible drug binding site can provide information on whether the target is druggable. Targets such as aspartic acid proteases may be considered undruggable based on the information, but while being difficult have yielded drugs for hypertension (aliskerin, renin inhibitor [9]), and HIV (various [10]). β -Secretase as a target for alzheimers [11] is a possible higher hurdle since the target of interest is now located in the CNS and drugs will have to cross the blood brain barrier. Perhaps, rather than discard targets on ADMET space grounds, appropriate pathways to a drug should be identified at this stage such as a biological or small chemical approach after the key points of

1. Pivotal point in pathway of disease effects or symptoms.
2. Effects of inhibition or activation of target not likely to be attenuated by competing pathways.
3. Likely overall beneficial effect influenced by interaction with drug molecule in most (all) patients.

4. Sufficient diversity for selection against other receptors including subtypes.

Target identification and selection (1–4) are exemplified in the postgenomic era by CCR5 and its role in AIDS [12,13]. A deletion in the CCR5 gene called *CCR5* Δ 32, results in a nonfunctional CCR5 protein that is not expressed on cells. People with two copies of the *CCR5* Δ 32 gene are resistant to HIV infection. The CCR5 protein allows a pathway for virus to enter the cell and a rational is therefore to produce an antagonist to mimic deletion of the gene. Encouragement for possible success with a small molecule is provided by CCR5 being a cell surface receptor of the family of nonaminergic GPCRs (G-protein-coupled receptors) which have been successful targets in a number of drug discovery programs. The genomic information also allows an indication of likely safety outcomes in this approach since those carrying the *CCR5* Δ 32 gene are otherwise healthy. This target has produced a recent drug maraviroc (III in Fig. 1.1) in the fight against AIDS. Points 3 and 4 are listed above, unfortunately are often only realized late in the discovery/development/product cycle. For instance, alosetron [14] was a selective 5-HT₃ antagonist. The rationale for the drug was the role 5-HT₃ antagonists have in suppressing the reflex colonic motor function in response to food ingestion. This reflex in diarrhea-predominant irritable bowel syndrome (IBS) is exaggerated resulting in cramping and diarrhea. The drug's side effects were noted as constipation. Wider use in patients after marketing produced several cases of ischemic colitis. Constipation can facilitate the development of ischemic colitis by increased colonic intraluminal pressure compressing the mucosal vessels and impeding circulation. Cilansetron, another 5-HT₃ antagonist, shows identical rates of ischemic colitis indicating that the effects are target related and not drug molecule specific. Although withdrawn, alosetron has been reinstated using very strict labeling and prescriber/patient practices. The antiobesity agents [14] were withdrawn for heart defects. Fenfluramine and dexfenfluramine bind weekly to 5-HT receptors and the major *N*-deethylated metabolite norfenfluramine is responsible for the pharmacological activity. The drugs reduce appetite by activating 5-HT_{2C} receptors via the metabolite. The metabolite is not selective and also activates the 5-HT_{2B} receptors on heart valves and pulmonary artery interstitial cells causing the formation of proliferative fibromyxoid plaques. While antagonists of subtypes of receptors are “routinely” possible there are considerably more demands to obtain selective agonists and the lack of a selective 5-HT_{2C} receptor agonist for obesity treatment may testify to this.

When a number of targets are being prioritized then it seems appropriate to consider the possibility of the binding site yielding molecules fitting within the confines of ADMET space.

Series/lead identification comprising HTS or fragment-based approaches followed by chemistry follow up is the first opportunity to gain actual experimental data, rather than theoretical. Considerable debate occurs as to how useful ADMET data is at this stage rather than physicochemical properties. The principal concern is that the molecular template, while giving potency and selectivity is flawed from an ADMET viewpoint and despite manipulation of the structure will not give favorable oral drug properties. Should lead molecules, therefore, be screened for ADMET properties to exclude them as leads or merely to show areas of improvement. Should the areas of improvement be prioritized early on

TABLE 1.2 Comparison of the Hydrophilic Drug Atenolol (log *D* 7.4–1.7) and the Lipophilic Drug Propranolol (log *D* 7.4–1.2) Illustrating the Need to Compare All Aspects of Screening Data to Choose Compounds

	Affinity pA ₂	Renal CL _i (u) (ml/min/kg)	Metabolic CL _i (u) (ml/min/kg)	Vd(u) (L/kg)	Half-life (h)	Daily dose (mg)
Atenolol	6.5	2	—	1	3–5	50–100
Propranolol	8.3	—	470	50	3–5	30–90

or should selectivity and potency be paramount until reasonable improvements in this area are seen.

- Compound identification comprising series/lead development followed by development candidate selection. At this stage, the use of ADMET data is unarguable. Most compounds will be close to the required potency and selectivity and usually one or two ADMET properties are being optimized. Potency and selectivity values should not be divorced from ADMET values and probably each compound should be evaluated in a horizontal manner obtaining full data. This is exemplified in Table 1.2 where two very successful β -adrenoceptor antagonists, with very different physicochemical, biological, and clearance properties, are compared. Owing to the compensatory nature of some of the processes the dose and dosing frequency of both drugs are very similar.

1.6.2 Is Drug Discovery a Linear or Nonlinear Process?

It is impossible to change one aspect of a compound's properties and not affect other properties. This interdependence of processes for the delivery and performance of an oral drug is the reason that drug discovery takes a long and somewhat circuitous and meandering route to the goal of a drug candidate. While many of the changes turn out to be deleterious, there is a counterside. Occasionally, this process works for the drug discoverer and a single change can turn an unproductive series to one that produces a drug candidate. The discoveries of amlodipine and fluconazole [15] contained a single chemical change or concept that led to very successful drugs. Unlike most other dihydropyridines calcium channel antagonists amlodipine has a basic primary amine side chain. Differentiating fluconazole was the introduction of a second triazole. Much of the thinking was to mainly to address solubility issues in the lead compounds nifedipine and ketoconazole. These were intuitive steps, based on the knowledge of the physicochemical nature of the new group and some freedom to retain activity by substitution in the selected region. These groupings dramatically enhanced the volume of distribution for amlodipine against other dihydropyridines, leading to a much longer half-life suitable for once a day administration. The bis-triazole series, of which fluconazole is member, had greatly improved solubility and at the lipophilicity of fluconazole (Log *P* 0.6) very little metabolism. Clearance was by glomerular filtration, with about 60–70% tubular reabsorption by passive reabsorption, again leading to a long half-life due to the low clearance value. However, there is an important corollary to this in that the lead compounds and lead series always were reasonably placed in ADMET versus target space.

Marviroc's discovery followed a more linear approach as the drug's discoverers worked through balancing permeability for oral absorption, rate of metabolism, and IKR

channel activity. The lead series and eventual drug are close to the edges of ADMET space versus target space. Screening in terms of permeability and metabolism was provided on almost all compound synthesized once sufficient potency had been attained in the lead series to see actual antiviral activity against the HIV virus (preclinical proof of concept).

The dilemma of all discovery projects is that the future is not predictable and the question is how far should progress be made before termination of a compound series or even a project. *N*-(1-(3,5-Dichlorobenzenesulfonyl)-2S-methyl-azetidine-2-carbonyl)-L-4-(2',6'-dimethoxyphenyl)phenylalanine was optimized to be a potent inhibitor of the (VLA) antigen-4 [16]. In terms of ADMET, space versus target space the properties dictated were not promising and the compound has physicochemical properties consistent with poor ADMET characteristics: molecular weight 607, PSA 131, log *P* 5.6. The compound was rapidly cleared in rat with values consistent with very high extraction by the liver (clearance equal to hepatic blood). In this particular case, further experimentation continued to show that the clearance of the compound was a result of the multiple processes of metabolism by oxidation and glucuronidation and biliary excretion of the parent molecule. The major contributor was the active hepatic uptake of parent compound (the compound was shown to be a substrate of the rat organic anion transporter, Oatp1b2) and metabolism did not influence clearance but determined excreted fate. The lead series was abandoned after these experiments.

1.7 TOO EARLY OR TOO LATE

The dilemma is how easy is it to remove a particular ADMET liability of a compound late on in the discovery process. In general, most discovery programs of major pharmaceutical companies have a screening cascade incorporating ADMET data into the earliest stage of compound synthesis and these screens tend to be comprehensive and the data arrives in a hierarchical manner. Even in this situation, a question of weighting needs to be applied.

1.7.1 Induction Screening

Induction screening is of low value until some understanding of the likely potency and concentration response of the project compounds is established. Many compounds including the reference standards such as rifampicin, show effects at concentrations approaching or exceeding $1\text{ }\mu\text{M}$ in *in vitro* systems. A detailed comparison of *in vitro* screening data and clinical results confirms that EC_{50} or maximum responses to an agent are of little value in determining which compounds will cause induction in the clinic. Only when *in vivo* exposure in humans can be determined (C_{max} or AUC plasma concentration data) can the compounds be correctly ranked. For instance, verapamil, which is not a clinical inducer, has an EC_{50} of $3.2\text{ }\mu\text{M}$ while phenytoin and carbamazepine, which are clinical inducers, have EC_{50} values of 8 and $15.6\text{ }\mu\text{M}$, respectively. The difference between the compounds is due to the clinical dose and resultant plasma concentrations which for the anticonvulsants are some two orders of magnitude greater than the calcium channel blocker. The structures of clinical P450 inducers of CYP3A4 show no obvious SAR and even detailed analysis suggests that the only common feature is some degree of lipophilicity. This is perhaps to be expected

from what is essentially a weak interaction between the compounds and the receptor [6,7]. In the absence of any other guidance, it is suggested that any induction screening is postponed if target potencies are below 50 nM. Because of the promiscuity of the receptors and the higher doses used in preclinical safety assessment, induction is a common finding and should not be viewed as a failure in screening. Moreover, owing to differences in receptors animal findings are not extrapolatable to the clinic.

1.7.2 Inhibition of CYP450 Enzymes

Similar comments can be made about the value of the data until an *understanding* of the likely potency and concentration response of the project compounds is established. However, unlike CYP3A4 induction, some structural features are associated with highly potent CYP inhibitors, both reversible and to a lesser extent irreversible. The presence of unhindered nitrogen in a saturated ring system (pyridine, imidazole, triazole) may result in the lone pair of the nitrogen being able to form a ligand interaction with the heme of the CYP450. Many of the potent CYP450 inhibitors bind in this manner and the interaction adds 6 kcal to the binding energy. This interaction is the basis for the action of azole antifungals and a number of aromatase inhibitors. As this interaction is commonplace and invariably leads to highly potent inhibitors such functionality is best avoided from the outset. In the case of the discovery of maraviroc, the original HTS hit and lead compound possessed an imidazopyridine [12] leading to very potent CYP450 inhibition. Replacement of the functionality occurred early on with benzimidazole (Fig. 1.1) and eventually a substituted triazole.

Mechanism-based time-dependent inhibitors form complexes with the heme moiety of CYP450 or bind irreversibly to the protein. Tertiary amines and their metabolism products classically are heme interactants, while irreversible protein binding inhibitors (suicide substrates) are classically formed by conversion to highly reactive short-lived metabolites.

Imidazole ring systems are also prevalent in mechanism-based time-dependent CYP450 inhibitors, although the relationships are more complex and are not accompanied by a mechanistic understanding [15]. Sufficient information is available to allow *in silico* filtering of compound structures to determine possible avenues which may lead to this problem [17].

1.7.3 Solubility, Permeability, and Metabolic Stability

Although a molecule has different properties, the three key factors that characterize an oral drug are intertwined by the physicochemical properties that define them. Increasing lipophilicity [which will often provide potency increases (see above)] will usually increase permeability and also increase the rate of metabolism while lowering solubility. This balancing act is a pivotal part of SAR development of a project and starts at the time of the lead series identification. Maraviroc [12] exemplifies the route from a lipophilic metabolically unstable lead to molecules with groupings such as triazole incorporated to counter the high rate of metabolism. The lower lipophilicities gave better metabolic stability but demonstrated low rates of flux in Caco-2 cells and resultant poor oral absorption. The eventual and successful development candidate maraviroc was a compromise of these properties but had sufficiently good pharmacokinetics to promise an IC_{90} on a reasonable oral drug regimen (300 mg od or bd).

As a general rule, lead compounds show rapid metabolism and hence high clearance is a widespread problem. The above example used the lowering of overall lipophilicity as a method to get stability; the other common tactic is the removal of vulnerable functionality or the introduction of blocking groups, particularly halogens, after identifying the sites of metabolism. This tactic forms an almost classical screening synthesis cycle, with potency, selectivity, flux, and overall metabolic rate being provided alongside and site of metabolism. This cycle is possible now because of the development of mass spectrometry technology. The cycle can be extended to use computational prediction of likely metabolites and then monitoring of these in high throughput manner [18]. The software, in this case MetaSite, is only 55% predictive of the compounds primary site of metabolism. However, by analyzing in addition 2nd and 3rd order rank predictions, the combination of *in silico* selection of likely metabolites and then monitoring these *in vitro* the method provides a favorable screening performance. The data on site of metabolism can usually not be provided on the same number of compounds. Typically, labile sites are explored alongside other sites in the generation of SAR. Intrinsic clearance data are calculated by screening compounds in human liver microsomes. This process is shown in the work on corticotropin-releasing factor-1 (CRF1) receptor antagonists [19]. The major sites of metabolism in the initial lead compound (potency 0.26 nM) were O-demethylation of both the methoxy groups (Fig. 1.2). These two positions were found to be the major sites of metabolism in all compounds generated and intrinsic clearance was influenced mainly by substitution at these sites. The 1-(1-cyclopropyl)ethyl group was selected as a stable (but less potent) alternative offering scope for potency improvements. The other labile *O*-methoxy position showed lower intrinsic clearance when replaced with groups such as trifluoromethoxy, trifluoromethyl, difluoromethoxy, chloro, cyano, and ethoxy. One of the difluoromethoxy substituted compounds combined potency ($IC_{50} = 1$ nM), functional antagonism, selectivity, and metabolic stability (Fig. 1.2).

1.7.4 Plasma Protein Binding

There is no common consensus and there are many misconceptions around protein binding and unbound drug. This arises because in a static *in vitro* test, the addition of

Figure 1.2 Corticotropin-releasing factor-1 (CRF1) receptor antagonists. The major sites of metabolism in the initial lead compound were O-demethylation of both the methoxy groups. These positions were stabilized by incorporations of the groupings shown.

albumin of plasma will often decrease the apparent potency of a drug. In this case, the change in free fraction directly relates to the concentration of free (unbound) drug. Because the addition of serum or plasma proteins is common in many assays, a biased view of compound affinity and potency may arise. Moreover, the static *in vitro* situation is then directly extrapolated to the dynamic *in vivo* situation and a belief formed that protein binding will similarly attenuate the effects of the drug. These beliefs drive a discovery project to attempt to lower plasma protein binding and this in turn requires plasma protein binding data to be available alongside data on potency, metabolic stability, permeability, and so on. If we concentrate on oral drugs, dosed to steady state unlike the static *in vitro* system, free concentration *in vivo* is not dependent on free fraction but on intrinsic clearance. The simple analogy is that if plasma protein was added to a clearance assay, and the drug is plasma protein bound, then there will be a lower rate of drug disappearance directly proportional to the reduction in potency. When the drug binds to proteins in a reversible manner the aqueous concentration of drug will be lowered by the amount bound. This will of course reflect the concentration of drug interacting at the receptor, but it will also lower the amount of drug interacting with the clearance enzymes: fewer drugs will be transformed per unit time. Thus, reversible interactions with proteins (or the phospholipids of membranes) will proportionately give lower drug concentrations than no interactions, but those concentrations will be sustained for proportionately longer. In pharmacokinetic terms over a defined period (the dosing interval) reversible interactions with proteins will lower maximum concentrations ($C_{\max}$) or aqueous drug but raise minimum concentrations ($C_{\min}$) to the exact extent that the average concentration (C_{av}) will be unchanged. Because the enzyme kinetics are essentially unchanged, providing first order is observed, daily dose is unchanged. Changing protein binding will not usually be reflected in changes in daily dose size to achieve the same average free drug plasma concentrations (although frequency of administration could be affected) [20]. Essentially, when all the processes of drug metabolism are modeled then $\text{AUC}_u = F_{\text{abs}} \cdot F_{\text{gut}} \cdot \text{Dose}/\text{CL}_{\text{int}}$, where AUC_u is the unbound drug area under the plasma concentration curve, F_{abs} is the fraction absorbed, F_{gut} is the fraction metabolized by passage through the gut wall (gut first pass) and CL_{int} is the intrinsic clearance. In the discovery setting, the latter is routinely assessed during metabolic stability screening (see above). Note that the fraction unbound is not present in the equation. It needs to be determined, however, at the stage when *in vivo* experiments are performed to complete the right-hand side. AUC_u is easily converted to C_{av} (average plasma concentration over specified time) by dividing AUC_u by time. C_{av} is a more useful parameter as it allows direct comparison with *in vitro* potency measurements [21].

1.8 INTEGRATION OF *IN VIVO* AND *IN VITRO* DATA

While *in vitro* data provides most of the ADMET data to a discovery project *in vivo* data is vital to ensure that what is being generated *in vitro* is consistent with what is observed *in vivo*. A major concern is around clearance processes. Table 1.1 indicates that highly permeable compounds are cleared metabolically and microsome data can be reliably applied. Exceptions to this include compounds with functionality likely to be metabolized by systems not present in microsomes such as aldehyde oxidase. This is one of several enzymes besides cytochrome P450 involved in the

oxidative metabolism of drugs [22]. Aldehyde oxidase [23] catalyzes the oxidation of aldehydes to carboxylic acids. Most importantly for drug discovery it catalyzes the oxidation of carbon–nitrogen double bonds present in aromatic azaheterocyclic compounds. Reliance on microsomal systems may give false indications of stability since the enzyme is soluble, and not bound to the endoplasmic reticulum, and thus appears in the supernatant. Aldehyde oxidase activities in dog are unusually low and strain dependent in rats so *in vivo* experiments may also be misleading.

Similarly, microsomes are normally fortified for oxidative metabolism only and direct conjugation of a substrate will not be observed. This suggests that for any compounds containing functionality likely to be labile to conjugation enzymes (hydroxyl, phenols, etc.) hepatocyte screening should also take place.

For less permeable compounds, the possibility of transporter involvement in clearance becomes likely. This interplay unless understood may lead to false assumptions about project priorities. For instance, the compound *N*-(1-(3,5-dichlorobenzenesulfonyl)-2*S*-methyl-azetidine-2-carbonyl)-L-4-(2',6'-dimethoxyphenyl)phenylalanine referred to above [16] was metabolized by oxidation and glucuronidation but when examined *in vivo* the major contributor to clearance was the active hepatic uptake of parent compound by a liver transport system. Reliance on microsomal or hepatocyte data may have led the project to attempt to stabilize the metabolic lability of the compound. The fate of the series, however, was largely determined by the physicochemical properties and their effects on permeability and transporter affinity.

1.9 WHEN ALL ELSE FAIL—USE AND ABUSE OF PRODRUGS

Often in medicinal chemistry programs, a stage is reached where many criteria for a molecule have been met, but certain elusive properties are unobtainable in the current series. Rather than search for an alternative series, attempts are made to produce a labile chemical derivative that yields the active drug at efficacious concentrations. These labile forms are called *prodrugs* [24] and have been attempted in a variety of forms to address solubility, permeability, clearance, and selectivity issues. Prodrug moieties have been added to molecules to

1. increase water solubility to aid dissolution, or to allow parental formulation;
2. increase permeability to aid absorption;
3. improve systemic pharmacokinetics by decreasing maximum concentrations and increasing drug half-life;
4. improve therapeutic index by targeting a drug to a tissue or cell type.

Actual examples of prodrugs successfully designed, developed, and marketed are largely limited to the first two categories.

The actual form of the prodrug varies. Testa [25] defined the chemical criteria that may be used to classify prodrugs:

- Bioprecursors, which do not contain a promoiety, yet are activated by oxidation, reduction, or hydrolysis.
- Carrier-linked prodrugs, where the drug is linked to a carrier and activation occurs by hydrolysis, oxidation, or reduction.

Macromolecular prodrugs, where the carrier is a macromolecule such as poly-ethyleneglycol.

Drug–antibody conjugates, where the carrier is an antibody, for instance, one with affinity for a particular tumor cell.

A number of drugs are prodrugs and termed *bioprecursors* but are not actually created by design including omeprazole, simvastatin, lovastatin, and clopidogrel. Many of these types of drug were discovered and developed without knowledge of the bioprecursor role. Clopidogrel's mechanism of action, as an example was not discovered until 2000 although US approval by the FDA was granted in 1997. The bioprecursor role of clopidogrel is the generation of its 2-oxo metabolite a metabolite, which hydrolyzes to a reactive thiol that can bind covalently to platelet ADP receptors and inhibit platelet aggregation [24].

To increase water solubility addition of water soluble functionality by pegylation and phosphate esters has been used. A recently marketed example of phosphate ester prodrugging is Fosfluconazole, a prodrug of fluconazole, an azole antifungal agent. The hydrolysis of fosfluconazole to fluconazole is catalyzed by alkaline phosphatases, which reside in most tissues especially the kidney and liver. Fosfluconazole is over 40 times more soluble than fluconazole, allowing it to be administered by bolus injection. The water solubility increase is due to a combination of intrinsic hydrophilicity and ionization [24].

The vast majority of successful prodrugs increase membrane permeability to allow oral absorption. These drugs conform to the ADMET space requirements in terms of polar surface area but are not lipophilic enough.

Prodrugging and acid function does little to mask polar functionality (same for alcohol groups) since the esterification of a carboxylic acid reduces PSA by only 11 Å². Thus, potential prodruggable molecules need to conform to PSA requirements prior to prodrugging. While this may be critical in some cases, this is a relatively small reduction and not what is envisaged in the scope of “masking” of polar groups. Major effect of esterification is to render the ionizable carboxylic acid neutral. The overall effect on lipophilicity is a combination of the loss of ionization and the intrinsic lipophilicity of the promoiety. For an acid of pK_a 3.4, approximately 4 log units of lipophilicity will be added to the log *D*_{7.4}. As a guide, therefore, the potential candidate needs a PSA less than 150 Å² to render a possible successful campaign [24].

Targeting a drug to a particular protein usually involves synthesizing a peptide or antibody delivery conjugate. These can show success *in vitro*, but usually fail *in vivo* for a number of reasons. Critical to success is the interplay of rates including [24]:

1. clearance of the drug conjugate from the systemic circulation;
2. rate of uptake by target;
3. rotency of drug;
4. release of drug in or at the target;
5. disappearance from target of the drug;
6. systemic clearance of the drug

Each of these factors is critical and needs to be precisely defined. For instance, for 2 and 3 many attempted delivery systems rely on an antibody conjugate and internalization. The antibody will often have subnanomolar affinity, whereas the drug may only

have micromolar activity against the target. This type of approach places unrealistic demands on the other factors even allowing that the antibody may be able to deliver more than one molecule of drug [24].

1.10 DEVELOPMENT: HUMAN METABOLISM THE PIVOTAL STUDY

Once a candidate is submitted for development a well-documented series of studies are conducted linking preclinical and clinical studies together. A pivotal study that causes much debate is the human metabolism study. This normally uses a radiolabeled version of the candidate drug. The emphasis of this study has changed with time but can be defined as a part of understanding the PK/PD (pharmacokinetics/pharmacodynamics) of the drug. It can be broken down into two elements: circulating and excreted metabolites. Smith and Obach [26] have suggested the primary purpose of these:

Circulating metabolites are of interest primarily because they can directly and probably reversibly interact with macromolecules, particularly proteins and cause a change in conformation and function of the protein to elicit a biological effect (beneficial or hazardous). These effects can be similar and additive to the parent molecule or may in some cases be different. Identifying and analyzing these metabolites in the same matrix as the parent allows concentrations to be measured and thereby assessment of PK/PD.

Excreted metabolites are of interest primarily, in human, because they allow the proportion of the parent converted to a particular metabolite to be determined and thereby support the *in vitro* enzymological evaluations for population variations and drug–drug interactions. In addition, they allow the detection of the downstream products of reactive metabolites and, moreover, allow an estimation of the amount (mass) formed. From a technical viewpoint, excreted metabolites often allow an easier workup of sample (than circulating metabolites) for detailed structural analysis and in some cases even yield sufficient sample for biological testing.

The species used in preclinical safety studies are also studied in this manner to allow comparisons with the human data. A variety of standards have been suggested for the comparison but clearly a metabolite present in much higher concentrations than seen in preclinical testing raises concerns and needs careful and thoughtful consideration. To obviate a late stage problem, there is considerable benefit in conducting the human metabolism study early; however, sufficient information needs to be available to make this expensive study pivotal. The most important factor is the clinical dose range, until this is known metabolism studies may be of a limited value. This information begins to emerge at the end of phase 2A or “proof of concept” studies, and it may be that the most opportune time is following these studies in parallel with phase 2B clinical studies. Various designs are employed but the following considerations need to be incorporated:

1. Polymorphically expressed enzymes: does the design need to incorporate representative variants in the volunteer population.
2. Single or multiple doses: can single dose results be extrapolated or does the design need to incorporate a steady state regime. An example would be a clinical enzyme inducer which could modify its own metabolism.

3. Unlabeled fragments of the molecule: depending on the site of label novel chemical matter may be liberated as unlabeled material. Should cold assay technology be used?
4. Does the radiolabel become incorporated into intermediary metabolism, does this render the use of a label unethical.

1.11 SUMMARY AND FUTURE PERSPECTIVE

The component parts of ADMET screening and their relative importance will continue to be discussed and debated in the foreseeable future. Most of the screening systems are now relatively generally established, but as this chapter tries to emphasize may be applied with the wrong emphasis or timing. There are considerable gaps in the systems to understand fully drug transport, something becoming more important as target and ADMET space ensure less permeable compounds. A part of the problem is the promiscuous SAR of the proteins, the difficulty of establishing how much of the protein is present, and the complexity of transport kinetics [27].

A second factor is the outsourcing and packaging of drug screens. As cost of research becomes an issue it is possible to design compounds in one place, synthesize them in another and screen them in a third. These places may represent different countries and even continents. The concept of a drug discovery team with representatives of the various disciplines intimately supervising the practical aspects becomes lost. Screening becomes a checklist, rather than a bespoke science and the danger of inappropriate data is maximized. Project objectives need to be agreed and careful examination of the appropriate screens and screening sequence conducted. Data from screens becomes available at different times and it is possible that the most rapid screens may disproportionately influence a project rather than the most important screens.

2.1 INTRODUCTION

The oncology market is the fastest growing in the pharmaceutical industry, yet oncology still has one of the poorest records for success in clinical development, partly due to the less than optimal correlation between nonclinical models and the disease in humans [1]. Growth of the market is being fueled by the magnitude of the disease globally; currently, 25 million people are afflicted with cancer worldwide. The World Health Organization (WHO) predicts that cancer rates may increase by 50% from 2000 to

2015. The Association for International Cancer Research (AICR) estimates that by 2020, there will be 10 million deaths from cancer per year. Even in developed nations, ~50% of patients diagnosed with cancer will eventually die of this disease. In the United States, cancer is the second leading cause of death by disease, one of every four deaths—and is exceeded only by heart disease. Approximately 570,000 Americans are expected to die of cancer each year, which equates to more than 1500 people a day. Nearly 1.4 million new cancer cases are diagnosed annually.

2.2 CYTOTOXICS

For several years, drug discovery efforts have focused on cytotoxics, compounds that block essential cellular functions and kill dividing cells [1,2]. These agents have included those designed to interfere with precisely defined physiological processes and those with pleiotrophic mechanisms. Examples of mechanisms in the first category include metabolite synthesis (e.g., methotrexate), microtubule polymerization (e.g., Taxol), and chromosome topology (e.g., irinotecan). Pleiotrophic molecules include those considered to be DNA-modifying (e.g., cisplatin). The therapeutic margin of these compounds is typically assessed as the differential between on-target effects in cancer cells and on-mechanism effects in normal cells. Dose response and distribution within tumors and normal tissues result in estimates of the therapeutic window (margin between efficacy and toxicity), and these estimates are studied in animal models and early clinical trials. Another class of anticancer drugs includes antihormonal agents such as estrogen receptor modulators (e.g., tamoxifen) and aromatase inhibitors (e.g., letrozole) [1].

2.3 TARGETED THERAPIES

There is a rapidly growing pipeline of targeted therapeutics designed to modulate single or multiple targets known to be important in cancer [2]. Accordingly, there has been a trend to move away from molecules with broad cytotoxic activity to more molecular targeted therapies [3,4], particularly in small-molecule research and development. Therapeutics of all types are now being developed in a targeted fashion, keying in specific molecular targets and specific signaling transduction pathways [2,3]. It is possible that broader therapeutic windows may be seen with these types of agents, particularly, if the specificity in targeting is limited to families of proteins prominent in tumors versus normal cells.

Biotherapeutics, another category of targeted anticancer drugs, represent a rapidly growing therapeutic modality. Biotherapeutics or biologicals are drug products where the active substance is produced or extracted from a biological source. These include recombinant hormones and proteins, monoclonal antibodies (mAbs), cytokines, growth factors, gene therapy products, vaccines, cell-based products, gene silencing therapies, tissue-engineered products, and stem cell therapies. A high proportion of biotherapeutic molecules under development and targeted for cancer therapy are mAbs, with most possessing IgG1 Fc designs with immunomodulatory function [5].

For targeted therapies including biotherapeutics, all effects attributed to the pharmacological mechanism, whether positive or negative, are considered to be related to

(i) binding or modulating a target (including unintended targets), (ii) the downstream effects from the modulation, (iii) targeting biological or signal transduction pathways, (iv) localized immune responses based on the design of the molecule, and (v) mechanistically based effects such as exaggerated pharmacology at the intended site of action or another tissue not intended as the primary site of action. Differences in molecules and effects also relate to the extent of target-related and nontarget elimination, receptor synthesis and turnover, molecule–receptor binding affinity, and molecule–receptor complex turnover [5].

Regardless of the type of therapeutic, the classic estimate of safety or therapeutic window in nonclinical mouse xenograft efficacy models, the ratio of tumor volumes in treated and control animals with the estimate of toxicity defined as *percent loss in body weight* (<10%) has carried on in the drug discovery field, even with newer targeted therapeutics [6]. Although this estimate has been used for decades, it fails to distinguish between on- and off-target effects or to differentiate between mechanism- and chemistry-based toxicities.

2.4 NONCLINICAL STUDIES: THE SHIFTING PARADIGM FOR TOXICITY TESTING

Nonclinical studies for anticancer drugs, which cover *in vitro* and *in vivo* studies, are designed to identify and quantify the pharmacological properties of the therapeutic, to understand the toxicological properties of the therapeutic including target organ(s) and dose (exposure)–response relationships, and to establish safe initial dose levels for the first exposures in humans [5]. First-in-human (FIH) guidance based on preclinical markers of safety and efficacy has been issued by the EMEA (European Medicines Agency) [7,8] and US Food and Drug Administration (US FDA) [9], covering both small molecules and biotherapeutics, and a new International Conference of Harmonization (ICH) guideline on nonclinical evaluation for anticancer therapies is pending [10]. These guidance documents can be interpreted as “limiting” the amount and extent of toxicology testing required to enter the first clinical trials, with the underlying thought that the best information for developing an anticancer therapeutic will come from experience in cancer patients. This is exemplified in the current concepts for FIH dose selection for biotherapeutics, which have evolved into a target-mechanism-based model (TMBM) utilizing exposure–response relationships from both *in vitro* and *in vivo* studies including (i) minimally effective exposure concentrations for biological activity (e.g., ED₁₀), (ii) pharmacologically active levels (e.g., ED₅₀) particularly important for FIH cancer trials, (iii) no observable adverse effect level (NOAEL) and/or toxicodynamic endpoint estimates from toxicology studies, and (iv) exposure- or concentration-related biomarker changes [5]. Ideally, these parameters are measured in the nonclinical studies, but in some cases, they are predicted via modeling or allometric extrapolation, such as in the case for estimated human doses and/or exposures. Dose escalation to a maximum tolerated dose (MTD) is a goal of phase 1 trials in order to select an optimal biological dose for phase 2, and most researchers are in agreement that nonclinical studies should be conducted, which allow such dose escalation to occur as rapidly as possible. In cancer patients, starting at a suboptimal or potentially subtherapeutic dose is not generally viewed as being acceptable

because there is an inherent desire to give each patient a potential therapeutic dose level [5].

2.5 EARLY TOXICOLOGY FOR DISCOVERY SUPPORT: HOW MUCH APPLIES TO ANTICANCER DRUGS

Several schemes for incorporating toxicity testing in the discovery process have been proposed with the objective of identifying potential side effects in humans and in animals used for pivotal toxicology assessments for regulatory purposes. Lead compounds or development candidates that pass through these “filters” increase the probability of success for a molecule. Screens, which include both *in vitro* and *in vivo* studies, are designed to be related to chemical reactivity or metabolic instability, unintended off-target effects possibly related to the unanticipated interaction with other targets or receptors, certain physicochemical properties of the parent compound and/or metabolites, and those properties that are related to the intended therapeutic mechanism of action, where unanticipated biological consequences or interaction with an unanticipated target takes place [11]. For the most part these are focused on understanding chemically related toxicity, where a correlation between chemical structure and potential toxicity is assessed [12]. Molecular mechanisms and the consequences of biological target modulation are typically reserved for efficacy and potency screening, particularly to attempt to understand the kinetics and dynamics of the compound at the target site [13]. Compounds or classes of compounds that are known to confer toxicity in a specific tissue will typically lead to an *in vitro* assay with results correlated with potential findings in either animal or human *in vivo* assessments. With a defined quantifiable endpoint and structural similarities in libraries, detailed quantitative structure–activity relationship (QSAR) modeling can be used as a predictive process for both efficacy and toxicity [11]. Therefore, early toxicity screening typically involves *in silico*, *in vitro*, and/or *in vivo* analyses and studies based on known toxicities that have either occurred in animals or resulted in slowing down or eliminating projects, where toxicities have occurred in clinical trials or where toxicities seen in patients after a drug reaches the market. The primary concern with screening assays is that they must be predictive, and the predictive endpoint must be human toxicity. If the goal of any program is to predict toxicity in rodents because rodents will be used in pivotal toxicology studies, then the toxicity induced in rodents must be relevant and predictive of the same effect in humans. Great effort is made in early screening on rank ordering compounds to filter out “bad actors” and increase the probability of selecting molecular structures that eliminate certain unwanted attributes. For the most part, these assays are done in human cell-based systems, which maintain genotype and phenotype [14], and even then there are several examples where the relevance of screening cannot be determined. This includes assays designed to understand the chemical interactions with the constitutive androstane receptor (CAR) and peroxisome-proliferator-activated receptor (PPAR) nuclear receptor families [15]. In addition, the difficulties of modeling and predicting toxicity from immunomodulatory drugs are well established [14,16]. One of the primary challenges in this field is that assays meant to be predictive are developed retrospectively based on experience, and as such, they tend to validate the previous finding and/or may be used to define a mechanism. Questions still remain as to the quality of some cell-based assays used prospectively for predicting potential toxicities with previously untested compounds.

2.5.1 Screening for Liver Toxicity

Hepatotoxicity is a major cause of drug failures both pre- and postapproval; however, the fact that several mechanisms can be involved and some liver toxicities are idiosyncratic (rare in occurrence) makes this a difficult task for accurate screening [11]. There are several systems in current use including primary cell cultures, immortalized cell lines, liver slices, and whole perfused livers [17,18]. The two most widely used methods use primary cells from freshly isolated hepatocytes from humans and animals used in preclinical assessments, and immortalized cells that over- or under-express certain phase I CYP450 and conjugating enzymes allowing the assessment of maximal production of reactive intermediates. Although not as widely used, differences in metabolism may be assessed when polymorphisms affect metabolic rates in certain individuals [18]. Cytotoxic screening with newer technologies to assess multiple parameters such as nuclear morphology, cell proliferation, plasma membrane integrity, and mitochondrial function in a high content screening format are also being used [19]. An advantage of this type of screen is the ability to couple with assays measuring mechanistic endpoints such as oxidative stress, DNA damage, apoptosis, and cell cycle inhibition, again in a high content mode via multiplexed platforms [19]. It should be pointed out that these types of assays work the best when used to rank order compounds rather than as a predictive assay for an individual compound. Computational models for liver toxicity have also been developed [20,21]; however, there remains difficulty when several different mechanisms of liver toxicity are represented by compounds used to train computational models. Using cell-based assays in a predictive mode, prospectively, still carries a level of uncertainty because of differences seen between species and individual differences noted in freshly collected hepatocytes [18,19]. Array “omics” technologies have been utilized in virtually all these assay formats but have had limited success when used prospectively [14]. These technologies may be of greater utility in defining specific mechanisms rather than as predictive assays. An important limitation is the number of cells needed for assays and the fact that results are based on average changes from several cells [22]. Important work by Cohen and colleagues [23] noted differences in protein response of human cancer cells to drugs using central dogma (CD) tagging in human H1299 lung carcinoma cells and time-lapse fluorescence microscopy. These changes involved rapid translocation of proteins specific to the mechanism of the drug and slower, wide-ranging temporal waves of protein degradation and accumulation. They provide an understanding of how cells that seem identical show different responses to drugs [22,23]. Technologies that measure responses in individual cells rather than averages of several cells (with cell to cell variations) may offer a promising way to understand both efficacy and toxicity in the same assay.

2.5.2 Screening for Cardiotoxicity

Cardiotoxicity in humans is another type of toxicity seen with several classes of compounds including targeted therapeutics. Screening for QTc prolongation has been established for several years, and multiple screening approaches are being required and employed in most major industrial companies globally. Cardiotoxicities from targeted therapies (other than QTc prolongation) are more difficult to predict in preclinical studies, as these types of effects lead to defects in left ventricular function and congestive heart failure. Several screening approaches have been used in an attempt to

prospectively predict cardiotoxicity using *in vitro* models, which include cardiomyocyte cell lines or primary cells [24]. Primary cells are typically ventricular myocytes from neonatal or adult rats. The merits and limitations of these two approaches have been discussed and it has been concluded that cell lines are inferior to primary cells because the mitochondrial electron transport system is the dominant source of energy in cardiomyocytes, whereas cell lines rely on glucose for energy generation [24]. These systems are sensitive and may produce a high degree of false-positive results and will not detect toxicity from direct effects on the vasculature [24]. Several *in vivo* models have also been used, including echocardiography in mice, pharmacologic stressor probes in rodents, catheterization for contractile dysfunction, and transmission electron microscopy in rodents. Prospective use of these techniques as an effective predictive assay has not been reported to any extent [24].

Early screening programs are usually company specific based on toxicities seen in internal pipelines but tend to include structure–activity relationship (SAR) (alerts) by computational tools [11], identification of reactive moieties in chemical structures using both computational and capture assays [20], and screening in model systems based on suspected target organs as noted above. Early *in vivo* studies are typically designed to explore linearity of dose versus exposure, which may include assessing different vehicles and their effect on bioavailability, rising-dose studies to explore dose versus overt toxicity, and preliminary studies (7–10 days) to establish high and low dose levels for definitive toxicology studies [12].

2.6 NEWER MOLECULAR TARGETS AND CANCER THERAPEUTICS

New targets are continually being discovered by molecular genetic assessments of cancer biology. Molecular targeted therapies are composed of novel therapeutic agents that target biologically important processes central to the development and progression of cancer and generally fall into the following categories [25]:

- *Single-Target Signal Transduction Inhibitors:* These include inhibitors of any single target (primarily) such as EGFR (epidermal growth factor receptor), mTOR (mammalian target of rapamycin), PKC (protein kinase C), Bcr/Abl [e.g., imatinib (Gleevec; Novartis), trastuzumab (Herceptin; Genentech/Roche), and panitumumab (Vectibix; Amgen)]. Imatinib is generally considered to be a single-target agent but it also inhibits PDGFR (platelet-derived growth factor receptor) α/β and KIT to some degree.
- *Multitargeted Inhibitors:* These include any agent with more than one therapeutic target [e.g., sorafenib (Nexavar; Onyx), sunitinib (Sutent; Pfizer), dasatinib (Sprycel; BMS), and lapatinib (Tykerb; GSK)].
- *Angiogenesis Inhibitors:* These include inhibitors of VEGF/VEGFR (vascular endothelial growth factor/VEGF receptor), uPA, and integrin families [e.g., bevacizumab (Avastin; Genentech/Roche)].
- *Epigenetic Modulators:* These include the histone deacetylase (HDAC) inhibitors [e.g., vorinostat (Zolinza; Merck)].
- *Cell Cycle and Apoptosis Targeted Agents:* These include modulators of CDK, Bcl-2, TRAIL, and Chk proteins [e.g., bortezomib (Velcade; Millennium)].

- *Immunomodulatory and Immunoconjugated Therapeutics*: These include the cancer immunotherapies and radioimmunotherapies [e.g., rituximab (Rituxan; BiogenIdec/Genentech/Roche) and gemtuzumab ozogamicin (Mylotarg; Wyeth/Pfizer)].

Agents that target (i) cell division by newer mechanisms, such as the aurora kinase and cyclin-dependent kinase inhibitors, (ii) protein turnover (e.g., bortezomib), or (iii) chromatin modification (e.g., HDAC inhibitors) have been referred to as *neo-cytotoxics* [1].

A market report on molecular targeted therapies by Datamonitor in October 2007 [25] identified 329 different targeted therapeutics in the developmental pipeline. Of these, 44 (13%) were classified as angiogenesis inhibitors, 45 (14%) were single-target signal transduction inhibitors, 65 (20%) were multitargeted inhibitors, 95 (29%) were cell cycle or apoptosis targeted agents, 64 (19%) were immunomodulatory or immunoconjugated therapeutics, and 16 (5%) were epigenetic modulators. Datamonitor forecast these targeted therapy candidates to realize an aggregate seven major markets' sales potential of \$6.03 billion by 2016. A report by Bioseeker in October 2009 [26] identified 409 protein kinase drugs (990 projects) either ongoing or recently stopped within the portfolio of 160 companies or investigators. The data included 133 identified targets, 200 drug target profiles, and 57 different cancer indications.

2.7 TOXICITIES OF TARGETED THERAPEUTICS

The increased interest in discovering and developing molecular targeted therapeutics has changed the focus of toxicities in patients away from traditional cytotoxic side effects seen with chemotherapeutics, which potentially changes the types of early toxicity screening programs that must be instituted in drug discovery and early development. It should be noted, however, that several targeted therapies do get approved as combinations with cytotoxic therapies. Early discovery-based screening in oncology drug discovery concentrates on chemical-based toxicity, where modifications of the structure of potential candidate drugs are accomplished during lead optimization, and mechanism-based toxicity, where a specific toxicity or tissue has been identified as being an issue to overcome during the lead discovery and development process. Various tiered approaches have been developed in industry, which include SAR structural alerts for toxicity (including genotoxicity), identification of reactive moieties in proposed chemical structures, and primary and secondary screening in model systems [11,12,17]. These systems have, among other endpoints, included novel approaches utilizing cytotoxicity as the defining type of toxic event [17,19,20].

Since many toxicities associated with molecular targeted therapies are associated with the actual mechanism for pharmacological targeting, these agents require a detailed understanding of the molecular aspects of the target, affected signaling pathways, and potential or unsuspected off-target toxicities that may be encountered. This raises the question of whether traditional toxicity screening programs and studies can or should be front loaded into discovery development programs of individual targeted therapies without a more complete understanding of how to monitor mechanistic toxicities where specific biomarkers of affected pathways may be needed. Realistically, the issue here is the lack of a clear understanding of the potential mechanisms and putative events

that trigger toxicities with molecular targeted therapies and the lack of defined and validated biomarkers. Biomarkers are defined as *objectively measured characteristics* that are useful as indicators of normal and/or pathological biological processes, or pharmacological responses to a therapeutic intervention. Biomarkers theoretically can help to determine whether the molecule reaches and modulates the desired target, whether it affects biological activity as intended, and whether this may lead to a desired or, in some cases, an undesired outcome [5]. Examples of the difficulties with mechanism-based biomarkers used for safety endpoints are seen with biomarkers of mTOR inhibition: phosphorylation of 4E-BP1 and S6K1. These biomarkers have been used effectively in animal studies and clinical trials showing dose-related modulation of downstream events from mTOR. However, adverse events in humans cannot be correlated *per se* with these mechanistic markers. Toxicities that occur in greater than 50% of patients receiving mTOR inhibitors (e.g., rapamycin) include mucositis, stomatitis, cold sores, pneumonitis, hypersensitivity reactions, and skin rashes. The mechanisms for these types of reactions have not been determined, although all are usually managed adequately. Hyperglycemia can be associated with a disruption of insulin signaling [27], which is seen more commonly with inhibitors of targets upstream of mTOR, such as PI3K.

2.8 TOXICITIES EMERGING IN CLINICAL TRIALS OR POST MARKETING

Human adverse events from therapeutics are typically discovered during clinical trials or after market approval where exposure to the drug is expanded dramatically. One important type of analysis focuses on toxicities that have resulted in market withdrawal of the drug. Several authors have surveyed drug withdrawals and offered detailed analyses of potential mechanisms of individual drugs and the factors leading to human toxicity [28,29]. In these reports the reasons for market withdrawal have been classified as (A) based on the primary pharmacology (A1) of the drug and its intended target or (A2) secondary pharmacology due to nonselective activity against nonintended targets; (B) based on an immunological mechanism, which includes several idiosyncratic toxicities; (C) based on a chemical reaction with tissue macromolecules with a rapid ensuing response, typically occurring via bioactivation to a reactive chemical moiety; and (D) delayed responses from mechanisms similar to (B) and (C) such as carcinogenesis and teratogenesis. Type (A), (C), and (D) toxicities are for the most part thought to follow classic dose–response relationships, which defines how screening studies are designed, whereas type (B) toxicities do not [14,29]. MacDonald and Robertson [14] reviewed specific reasons for the withdrawal of drugs from the US, Japanese, and European markets during 1998–2008 after finding that the two major reasons were hepato- and cardiotoxicity. Other reasons included psychiatric problems and addiction, gastrointestinal toxicity, muscle toxicity, renal dysfunction, accelerated carcinogenicity or death, mutagenesis, drug–drug interactions, hypersensitivity, and pulmonary hypertension. Mechanisms and molecular events associated with liver toxicities included mitochondrial toxicity, cholestasis, cytotoxicity from reactive metabolite, and unknown mechanisms for rare idiosyncratic hepatotoxicity. Cardiotoxicity was a result of alterations in ion channel function leading to QTc prolongation, altered valvular function, and arrhythmias resulting in fatalities [14]. Not surprisingly, screening programs within

the industry key in on these findings, with the majority of programs screening for genotoxicity, cardiotoxicity, and hepatotoxicity [11]. This generally includes all small-molecule programs regardless of the intended indication, and results from screening can be used repeatedly to generate “safer” SAR libraries either virtually or synthetically.

The other important assessments are generated from clinical trial data when this information is accessible. Considering small-molecule and biologic targeted therapies, Roberts and colleagues [30] assessed issues emerging during phase I in cancer patients with data gathered from journal articles and abstracts submitted to annual meetings of the American Society of Clinical Oncology (ASCO) presented from 1991 through 2002. The database included 213 trials with 6474 patients, where 47% of the trials involved targeted small molecules and biologics (combined together by the authors). There were approximately 4% objective responses in all patients and 137 deaths (~2%) of which 35 were classified as treatment related. The overall toxic death rate was estimated to be ~0.5%. Targeted agents had a lower death rate than cytotoxics. The overall serious toxicity rate was ~10%, with major categories from small molecules being hepatic and neurological. During the early period of the study (1991–1994), the odds of a patient dying was 10 times that of the latest period (1999–2002), and over time, there was an increase in safety but a decline in response rates in phase 1 trials. The authors discussed several theories for these findings, which included the opinion that more targeted small molecules and biologics appeared in the later time periods, which supports the rationale that targeted therapies are better tolerated than cytotoxics. It has become apparent over the last 10 years that toxicities associated with targeted therapies in cancer patients are, in fact, different from those seen with standard chemotherapeutic agents and several can be predicted from effects of modulating a specific biological target or multiple targets.

2.9 IMMUNOMODULATORY THERAPEUTICS

Immunomodulatory therapies are widely used in a number of diseases including cancer, autoimmune disorders, multiple sclerosis, and organ transplantation. During the years 1995 to 2008, 174 biotherapeutics (excluding vaccines) were approved for marketing; 136 in the United States and 105 in the European Union, with 67 of these approved in both regions [31]. The majority of safety-related regulatory actions taken in the United States and European Union were related to immunomodulatory effects, which lead to an increase in the risk of secondary and opportunistic infections during long-term treatments. These types of reactions are primarily detected post approval and not well predicted from animal studies. As an example, patients on immunosuppressant therapies display an increased incidence and severity of community-acquired pneumonias and viral infections [16]. The type of infection depends on the underlying defect in the immune system. Cell-mediated immunity involves the activation of phagocytic components of the immune system, natural killer cells, antigen-specific cytotoxic T lymphocytes, and the release of cytokines. Abnormalities in cell-mediated immunity often result in infections and illness called *opportunistic infections*. Opportunistic infections are caused by microorganisms that are usually subclinical or latent in individuals with normal immune function. These types of infections are those normally seen in patients with HIV/AIDS and/or who have undergone organ and stem cell transplant [16].

2.10 MOLECULAR CHALLENGES IN SCREENING TARGETED THERAPIES

This raises the questions pertinent to the title of this chapter: are there molecular challenges to the standard practice of front-loading toxicity screening and testing in the discovery and development of targeted therapies? If so, what are the challenges? Three distinct development approaches, which affect “front loading,” are currently used in the biopharmaceutical industry [12]. The major difference is when the decision is made to pursue full development of the lead compound or development candidate, which triggers full-scale process chemistry and development expenditures. In one scheme, full development starts when the development candidate is selected. This scheme is considered the fastest path to the market and follows the assumption that the drug will succeed. In other schemes, full development starts when all Investigational Drug Application (IND) work has been completed or at least when pivotal toxicology studies have been reported. This scheme imposes a risk-benefit decision based on preclinical data. With some exceptions, a hybrid of these two is the usual approach in the pharmaceutical industry, and this practice imposes the front loading of toxicity screening and testing in order to make the informed decision faster. In the third approach, full development starts when preliminary clinical information suggests an increased probability of success. This is the approach used by smaller companies in the biotechnology field, which then becomes the driving force behind additional funding or collaborative transactions with larger partners.

2.11 SIGNALING PATHWAYS IN CANCER RELATED TO TOXICITIES OF THERAPEUTICS

Because of the prominent role the EGF and VEGF pathways play in cancers and the continued information developing on toxicities seen with agents inhibiting these signaling pathways, these processes and drugs are highlighted in this chapter. Both targets and signaling pathways include small-molecule and biotherapeutic inhibitors representing both single- and multiple-target approaches. These signaling pathways are shown in Figs. 2.1 and 2.2.

2.11.1 Epidermal Growth Factor

EGFR is a transmembrane tyrosine kinase receptor, which maintains a pivotal role in regulating cell division and death. EGFR belongs to the HER family of receptors composed of four related proteins (EGFR(HER1/ErbB1), ERBB2(HER2), ERBB3(HER3), and ERBB4(HER4)). The HER receptors are known to be activated by binding to different ligands, including EGF, TGFA (transforming growth factor α), heparin-binding EGF-like growth factor, amphiregulin, betacellulin, and epiregulin. After a ligand binds to the extracellular domain of the receptor, the receptor forms functionally active dimers [EGFR–EGFR (homodimer) or EGFR–HER2, EGFR–HER3, EGFR–HER4 (heterodimer)]. Dimerization leads to the activation of the tyrosine kinase domain, which results in autophosphorylation of the receptor involving multiple tyrosine residues. This leads to recruitment of a range of adaptor proteins (such as Shc, GRB2) and activates a series of intracellular signaling

Figure 2.1 EGFR signaling pathway. Binding of ligands such as epiregulin and EGF dimerizes EGFR and activates it. ErbB2 (HER2) does not have to bind to any ligand with high affinity but is a preferred dimerization partner for other ErbB receptors. One component of EGFR signaling acts through the adaptor protein Shc, resulting in activation of RAS-RAF pathway and MAPK cascade. Another component acts through PLC γ and PI3K-Akt axis leading to cell survival. *Source:* Pathway map provided by Genego, Inc. (See color insert.)

cascades, which ultimately affect gene transcription. Gene transcription results in reduced apoptosis, cancer cell proliferation, invasion, and metastasis. These events also stimulate angiogenesis that reacts in relation to stimuli to create new blood supply (neovascularization) to developing or expanding tumors [32]. Major biological pathways mediate downstream effects of EGFR. The first pathway involves the RAS-RAF-MAPK pathway, where phosphorylated EGFR recruits the guanine nucleotide exchange factor via the GRB2 and Shc adaptor proteins, activating RAS and subsequently stimulating RAF and the MAP kinase pathway to affect cell proliferation, tumor invasion, and metastasis. The second pathway involves the PI3K/AKT

Figure 2.2 VEGF signaling pathway. VEGF-A binding to VEGFR2, a tyrosine kinase, initiates a cascade of signaling including phosphorylation of PLC γ and adaptor protein Shc. PLC γ in turn catalyzes the hydrolysis of phosphatidylinositol ultimately leading to the release of stored Ca. Signaling through Shc activates RAS pathway resulting in MAPK cascade and cell proliferation. Another component of the VEGF signaling pathway acts through the PI3K-Akt axis leading to cell survival. *Source:* Pathway map provided by Genego, Inc. (See color insert.)

pathway, which activates the major cellular survival and antiapoptosis signals by activating various nuclear transcription factors, including NF κ B (nuclear factor κ B). The third pathway, JAK/STAT, is also implicated in activating gene transcription associated with cell survival [32]. Anti-EGFR antibodies (e.g., cetuximab) bind to the extracellular domain of EGFR monomer and therefore block ligand-induced receptor activation by competing for receptor binding by endogenous ligands. Small-molecule EGFR inhibitors (e.g., gefitinib) compete with ATP to bind the catalytic domain of the kinase, which inhibits EGFR autophosphorylation and subsequent downstream signaling [32].

EGFR inhibitors cause certain types of skin toxicity, typically seen as a papulopustular rash in ~45–100% of patients given these drugs [33,34]. Interestingly, the skin effects have also been used as a biomarker of effect and potential efficacy of these drugs in the clinic. Other toxicities noted with EGFR inhibitors include ingrown nails, paronychia, xerosis [35], and ocular toxicities including changes in eyelids such as squamous blepharitis and in the tear film [36]. Understanding the molecular mechanism of dermal toxicity has led to the design of compounds that potentially rescue the downstream effects of signal inhibition. One such approach is the use of a potent phosphatase inhibitor, menadione, applied topically [33]. Other nonrash toxicities, including skin hyperpigmentation, xerosis, pruritus, hair growth, and color changes have been reported with targeted therapies [37].

2.11.2 Vascular Endothelial Growth Factor

VEGF plays a key role in new blood vessel formation and pathological angiogenesis such as in tumor growth, ischemic diseases, and macular degeneration. The increase in secreted biologically active VEGF protein from cells exposed to hypoxia, a potent inducer of VEGF, is linked to an increased transcription rate, mediated by binding of hypoxia-inducible factor-1 (Hif1) to a hypoxia responsive element in the 5'-flanking region of the VEGF gene. Secreted VEGF protein is a major angiogenic factor that regulates multiple endothelial cell functions, including mitogenesis. Cellular and circulating levels of VEGF are elevated in hematologic malignancies and are adversely associated with prognosis. Angiogenesis is a very complex, tightly regulated, multistep process. Current therapeutic approaches include the inhibition of angiogenesis stimulants (e.g., VEGF) or their receptors, blockade of endothelial cell activation, inhibition of matrix metalloproteinases, and inhibition of tumor vasculature [37].

Compounds that inhibit VEGF affect multiple signaling pathways in cells that regulate and maintain the microvasculature [38]. Side effects from inhibitors of VEGF signaling have ranged from overt cardiac effects to hypertension [15,24,38,39]. Molecules with varying degrees of cardiorelated effects include those with both single and multiple targets. Single-target agents include Avastin and trastuzumab (Herceptin; Genentech/Roche). Multiple-target agents include Nexavar (c/B Raf, VEGFR2/3, PDGFR α/β , KIT, FLT3) and Sutent (VEGFR1/2/3, PDGFR α/β , KIT, FLT3, RET, CSF-1) [22]. Although the mechanism of cardiotoxicity has not been fully elucidated, Fig. 2.3 shows a diagram where three anti-VEGF therapeutics, trastuzumab, imatinib, and sunitinib, share a similar signaling event, translocation of BCL2-associated X protein (BAX) to mitochondria in cardiomyocytes, which can lead to apoptosis [39].

2.12 OTHER TOXICITIES

Targeted therapies can also lead to renal toxicity since most of the biological pathways involved are expressed in the kidney. Related toxicities reported include hypertension and proteinuria [40]. Adverse effects can be manifested through single-target therapies primarily through pathway inhibition such as the p38 mitogen-activated protein kinase (p38MAPK) inhibitors [41] and the type 1 insulinlike growth factor receptor (IGF1R) inhibitors [42]. Multikinase inhibitors induce a number of toxicities

Figure 2.3 Schematic representation of putative molecular mechanisms of cardiotoxicity of three tyrosine kinase inhibitors in cardiomyocytes. A key signaling event common to all three inhibitors is the translocation of BAX to mitochondria, which is known to be involved in mitochondrial depolarization, ATP depletion, and cytochrome *c* release, which is a common mechanism in apoptosis. But in cardiomyocytes, the same mechanism could lead to toxicity. Detailed molecular events of cardiotoxicity due to kinase inhibitors remain to be classified. Trastuzumab is an ERBB2 antibody that reduces oncogenic signaling in breast cancer because of the overexpression of ERBB2(HER2) via PI3K-Akt pathways, ultimately leading to apoptosis. But in cardiomyocytes, pro-apoptotic signals may lead to cardiotoxicity. Imatinib is an inhibitor of ABL and blocks oncogenic signaling in CML through RAF-ERK and PI3K-Akt pathways, leading to apoptosis. But in cardiomyocytes, ABL, Abelson tyrosine kinase may have a survival function, and inhibition of ABL leads to activation of prodeath JNK pathway, ultimately leading to translocation of BAX and apoptosis. Sunitinib is primarily a KDR, kinase insert domain receptor (VEGFR2) inhibitor but also has several off-target effects such as inhibition of ribosomal kinase RSK, perhaps leading to inhibition of BAD, BCL2-associated agonist of cell death phosphorylation and eventual translocation of BAX to mitochondrion. *Source:* Adapted from Force T, Krause DS, Van Etten RA. Molecular mechanisms of the cardiotoxicity of tyrosine kinase inhibitors. *Nat Rev Cancer* 2007;7:332–344. (See color insert.)

where the commonality of toxicities between certain drugs is associated with common targets within a multikinase profile [43–46]. For instance, sorafenib and sunitinib target PDGFR, FLT3, VEGFR, as well as other kinases (see above), and share certain toxicities including cardiotoxicity. Toxicities of specific drugs are also influenced by the status of the patient and the type of cancer being treated. Several anecdotal reports appear in the literature that involve specific patient characteristics linked to toxicity, such as a case of plantar erythrodysesthesia in a patient being treated for non small-cell lung cancer, who was given low doses of sorafenib [47]. Although toxicities can be broadly based, the multikinase inhibitors are reasonably well tolerated as a class [43] and toxicities are becoming more predictable as use becomes more widespread.

2.13 DO CURRENT PRECLINICAL STUDIES PREDICT HUMAN ADVERSE EVENTS FROM MOLECULAR TARGETED THERAPIES?

Summaries of documents for four drugs submitted to the US FDA for registration purposes were examined to see if cardiovascular toxicity associated with VEGFR inhibitors and/or dermal effects from EGFR inhibitors were identified in *in vitro* systems or animal studies before clinical development [48–51]. Nonclinical studies on sorafenib (Nexavar) indicated a potential for cardiotoxicity primarily detected in safety pharmacology studies. Positive findings were seen in the *in vitro* hERG and action potential assays; however, there were no clear findings in dog telemetry studies or in a chronic one year study in which elevated CK (creatinine kinase) levels were observed. Limited histopathological findings in cardiac tissue were present in some animals in toxicology studies. In clinical trials, there was an increased incidence in hypertension versus control arms and, although rare, valvular disease and heart failure were reported as a cause of death in sorafenib arms. In addition, the drug was found to affect thyroid and parathyroid function and electrolyte imbalance from GI toxicity and diarrhea, both conditions that could increase the risk for cardiovascular toxicity. Force speculates that the overall rate of cardiomyopathy for sorafenib is low. On the other hand, the rate for cardiomyopathy with sunitinib (Sutent) is rated as moderate with hypertension and hypothyroidism seen as contributing factors. In preclinical studies, sunitinib caused both *in vitro* and *in vivo* cardiac effects including increased action potential duration in canine Purkinje fibers, blockage in hERG assays, and QTc prolongation in monkeys. In three- and nine-month studies on monkeys, reductions in heart rate and changes in ECHO parameters were seen, including left ventricular ejection time. There were also histopathological findings in individual animals, including capillary proliferation, myocardium vacuolization, or inflammation of the pericardium. Evidence of hemorrhage in various tissues was seen in both rats and monkeys. In clinical trials, decreases in left ventricular ejection fraction were also seen, which directly correlated with preclinical findings, as did incidences of hemorrhage in several tissues.

Preclinical studies with the EGFR inhibitors erlotinib (Tarceva) and gefitinib (Iressa) showed mechanistic evidence of dermal toxicity. With erlotinib, dermal toxicity was noted in mouse cancer xenograft models and in multiple dose studies in rats and dogs. In addition, ocular toxicity including corneal ulcerations was seen in longer-term dog studies. Dermal toxicity with gefitinib was seen in multiple dose studies in mice and dogs. Other toxicities seen with these compounds were almost universally related to the molecular mechanisms associated with the pharmacology of the drugs. This includes the generalized gastric toxicity leading to diarrhea seen clinically.

A number of other toxicities have been seen in animal studies with both single- and multitargeted compounds, including findings in the hematopoietic system, liver, kidneys, both male and female reproductive systems, bone, teeth, adrenal glands, pancreas, and changes in coagulation parameters. Common findings other than cardiovascular and dermal toxicities include bone marrow hypocellularity, incomplete epiphyseal closing and/or thickening of growth plates particularly in dogs, dentin alteration in juvenile animals, and osteodystrophy of the jaw in rats.

One conclusion that can be drawn from about 10 years of experience with targeted therapies is that rather than front-loading general toxicology studies, it would be more appropriate to design toxicology studies where the molecular mechanisms could be studied and related to potential adverse effects. For the most part, these toxicities

per se can be monitored effectively in early clinical trials, particularly when adequate pharmacokinetic/pharmacodynamic (PK/PD) correlations can be made. If general toxicology studies are not predictive of these molecular mechanisms because of the lack of definitive molecular assays, then additional time should be spent on developing biomarkers to monitor mechanisms in relation to adverse effects. In the ideal situation, assays developed for animal studies can be translated into assays used for clinical trials [5], but as noted earlier, these assays and direct links to toxicity are only starting to emerge.

2.14 EXPLORATORY AND PHASE 0 TRIALS IN CANCER PATIENTS

Several exploratory and phase 0 trial designs have been proposed and issued in a guidance by the US FDA [52]. In addition, a new ICH Guideline S9 is proposing a more abbreviated preclinical resting scheme for FIH oncology trials [10], and several exploratory approaches are currently in use. These include microdosing for preliminary PK information [53], screening studies for more than one compound to judge comparative bioavailability [52], radiolabeled studies at very low doses for distribution and elimination [53], and heavy-water labeling to probe fluxes through various biological pathways [54]. What distinguishes anticancer therapeutics in cancer patients is the ethical consideration that cancer patients should receive doses that have a chance to deliver an efficacious response [55]. Therefore, using low doses that are several multiples below the estimated therapeutic dose is not a preferred approach for FIH dosing in cancer patients but is, in fact, included in the phase 0 oncology designs [55]. In the NCI (National Cancer Institute) proposal [56], the essential rationale is the integration of PD assays into the first trial as a way to explore target modulation as evaluated with PK correlates [56]. These trials have been proposed to be conducted under an Exploratory Investigational New Drug (xIND) application. Since these trials are to be conducted in late-stage cancer patients, standard genotoxicity studies are not required; however, assessment of vital organ function, including cardiovascular, respiratory, and central nervous systems, should be done in animals and would normally be included in the general toxicology studies. Stand-alone safety pharmacology studies are optional under this proposal; however, because of the cardiotoxicity noted with several targeted therapies, cardiovascular safety pharmacology studies would normally be included. In the ICH S9 proposal, the animal toxicology studies essentially mirror the clinical dosing schedule. In the shortest clinical dosing scheme where the drug is given once every three weeks, single-dose toxicology studies will support the FIH trial. When the drug is given once every two weeks, toxicology studies can be designed as two-dose, 14 days apart, studies. The standard determination of an NOAEL is not considered essential in the preclinical toxicology studies, and demonstration of complete reversibility from all adverse effects is not considered an essential part of the supporting data. However, an assessment of reversibility up to a point is always included in supporting toxicology studies. Toxicology studies include rodent and nonrodent species, and a common approach for small-molecule therapeutics, including most targeted therapeutics, is to set a starting dose in humans at one-tenth the severely toxic dose in 10% of the rodents studied. If the nonrodent species (e.g., dog, monkey) is more sensitive to the drug than the rodent model, then the starting clinical dose is one-sixth of the highest nonseverely toxic dose. Since this new guidance is expected to be viewed on a case-by-case basis,

there are potential examples where the toxicology program to support the FIH trial could consist of rodent species only [10,52].

Changes in the requirements needed to initiate clinical trials with oncology therapeutics have occurred for a number of well-publicized reasons. Of major concern is the low success rate in this therapeutic category; only about 5% of INDs for new molecular entities in oncology make it past the investigational phase, which compares to ~10% in other therapeutic areas [56,57]. At issue is certainly the prolonged time line and costs of clinical trials, but at the heart of the problem is the lack of validated preclinical systems that accurately predict the efficacy and toxicity of new therapeutic agents and modalities [6]. These deficiencies include both *in vitro* and *in vivo* assays and models and have led both regulators and investigators to initiate procedures to move new drugs into clinical trials in cancer patients faster and develop both PK and PD endpoints in humans rather than rely on imperfect systems.

2.15 CONCLUSION AND FUTURE PERSPECTIVES

With the changing regulatory view on requirements for FIH dose selection for anticancer drugs, and the increase in discovery and development of targeted therapeutics, the concept of front-loading toxicology studies into the discovery and development programs with the intent on accelerating the development time line can be questioned from a scientific/molecular standpoint. This question is based on the belief that the modulation of specific targets, the goal of targeted therapies, directly relates to both efficacy and toxicity. Therefore, measuring markers of these events as related to exposure via PK/PD relationship modeling may in fact be a more rational way to accelerate a program to phase II, in particular, for phase II dose selection. However, maximizing benefit from this approach will require increased efforts to define and create assays for relevant biomarkers of biological activity and safety as PD endpoints. Currently, this has not been realized to the extent that this model can be applied to a majority of anticancer discovery and development programs. It is possible, however, that current programs could save and preserve (i.e., biobank) samples from nonclinical studies and correlate findings from these samples when molecular markers become established. This approach would create the molecular underpinnings of future anticancer programs related to the same molecular targets. It is tempting to speculate that there will be increased efforts on identifying and qualifying markers seen in preclinical studies with the aim of translating these to humans to provide rational estimates for FIH dose selection. A greater emphasis is expected to be placed on translating effects in animal models into patients in the first trials, and these trials are expected to be initiated with less toxicity testing than seen in the past. The increased use of PK/PD modeling to estimate exposure–response relationship in animal models and clinical trials will take on added importance with targeted anticancer therapeutics. The practice of front-loading toxicity testing to accelerate programs must be tempered with the realization that many toxicities of targeted therapeutics relate to the actual mechanism of action for efficacy. Whether mechanistic assays can be directly linked to toxicity in nonclinical studies has yet to be fully elucidated. Presently, the best approach is to make use of PK/PD relationship modeling across species and biobanking blood and tissue specimens of preclinical as well as clinical studies for future analysis. Early screening for chemical-based toxicity will continue to be performed as part of the

lead optimization process, and cardiotoxicity—other than QTc prolongation—should be incorporated early on with targeted therapeutics because of the complex cross talk apparent in multiple signaling pathways.

3.1 SUMMARY

Drug discovery is a time-consuming and expensive endeavor fraught with many glaring failures in clinical trials. Optimization of drug absorption, distribution, metabolism, and excretion (ADME) parameters continues to play an important role to ensure that the exposure is sufficient to achieve proof of concept, and ultimately efficacy, safely in clinical trials to address unmet medical need. This chapter provides an overview of various *in vitro* and *in vivo* ADME studies commonly employed in drug discovery. Emphasis will be placed on the dependence of ADME parameters on physicochemical properties. The literature has been reviewed to highlight key relationships. However, literature reviews mainly focus on retrospective analyses. Therefore, examples are

included to illustrate how these principles can be embedded in drug discovery and used in a prospective drug design fashion with an emphasis on finding the physicochemical “sweet spot” that balances various properties. *In silico* (ADME) models should be an integral part of design as well and the value of various models has been illustrated.

3.2 THE ROLE OF ADME STUDIES IN DRUG DISCOVERY

Determining drug ADME properties of drug candidates early on in the drug discovery process is critical for achieving drugs with optimal properties and, in particular, an acceptable dose and dosing regimen. Many people refer to the data presented in Fig. 3.1—the reasons for attrition in development in 1991 and 2000—to highlight the impact of early ADME studies and their positive impact on a significant reduction in attrition due to pharmacokinetic (PK) reasons. In the 1980s, inappropriate ADME characteristics were a leading cause of attrition in drug development (about 40% of drugs failed due to drug metabolism and PK reasons) and this was reduced to <10% in the 1990s [1]. The latter was confirmed by another analysis of drug development project terminations from 1992 until 2002 with ADME being cited as the reason for attrition in 14%, 17%, and 4% in phase I, II, and III, respectively [2]. Although this trend is undoubtedly real, it is important not to overinterpret these data and assume that ADME sciences are sufficiently mature. First, there were many anti-infectives in development in the 1980s with many of them failing due to poor PK and contributing to the statistics presented in Fig. 3.1. If anti-infectives are taken out of the equation, the reduction in attrition due to ADME reasons is less pronounced; the attrition due to PK reasons was 39% from 1964 until 1985, but this was reduced to 7% if anti-infectives

Figure 3.1 Reasons for attrition of drugs in development. *Source:* Data from Ref. 1.

were excluded [3]. Second, many compounds fail in development because they fail to illicit efficacy. Indeed, a key concern in the pharmaceutical industry is the very high attrition in phase 2 (>60% is quite common among the leading pharmaceutical companies and it is getting worse) and this is largely due to lack of efficacy or insufficient efficacy compared with standard of care [4,5]. However, in some cases, the lack of efficacy may be due to insufficient exposure and it is not inconceivable that efficacy may have been achieved if the clearance had been lower or absorption better. The latter is particularly worrisome because the clinical validity of the target may not have been properly assessed and, therefore, the decision to nominate a backup compound or not cannot be made in a reliable manner. Indeed, 12 of 44 phase 2 programs failed at Pfizer because no downstream pharmacological effect was observed in human and confidence that sufficient exposure was achieved to test the mechanism was low [6]. Third, some of the attrition due to toxicity may be metabolically mediated and, therefore, a greater understanding of the metabolic fate of drug candidates could influence survival in drug development. Moreover, the regulatory standards keep increasing with an increasing demand for ADME studies and a reduced tolerance for ADME-related issues such as drug–drug interaction and reactive metabolite formation. Thus, although the trend is very encouraging, it is critically important to continue to advocate early incorporation of ADME properties in the complex multiparameter optimization process in drug discovery and do so on an equal footing with potency, selectivity, toxicity, and so on. The important role of ADME properties is nicely illustrated by the “*stringent selection criteria*” presented by AstraZeneca in 2011 [7] and reproduced in Table 3.1 with the parameters having a direct bearing on ADME highlighted.

In vitro and *in vivo* ADME studies serve multiple roles in drug discovery:

- Determination of *in vitro* ADME parameters using cell lines and subcellular fractions from rodents, dogs, or monkeys to identify the best compounds for preclinical PK studies or *in vivo* proof of concept studies.
- Determination of plasma or tissue exposure to prepare for or to support interpretation of preclinical efficacy and toxicity studies.
- Determination of *in vitro* ADME parameters using human cell lines and subcellular fractions and *in vivo* ADME parameters from studies in rodents, dogs, or monkeys to predict human PK parameters and the propensity for drug–drug interaction.

TABLE 3.1 Stringent Selection Criteria Presented by AstraZeneca in 2011 [7]

Right Target Engagement	Link Between Target/Disease Predictive Biomarkers
Right tissue exposure	<i>Bioavailability and tissue exposure</i> <i>Human PK/PD prediction</i>
Right safety	Differentiating safety <i>Reactive metabolites</i>
Right patients	Scientific evidence in lead indication Stratification of patient population
Right commercial	Differentiated value proposition Embedded payer perspective

- Determination of the anticipated human efficacious dose using a combination of predicted human PK parameters and preclinical pharmacodynamic (PD) and/or efficacy studies.

Considerable progress has been made with the suitable incorporation of preclinical *in vitro* and *in vivo* ADME studies, but understanding the ADME structure-activity relationship (SAR) and the ability to effectively manipulate it in drug discovery is still problematic. Indeed, in many cases, it is easier to optimize potency and selectivity than the ADME properties, which provides further impetus to incorporate ADME in drug design early on. The following DMPK-centric strategies can have a positive impact on identification of compounds with superior properties and result in a reduction in the time spent in drug discovery:

- (continued) emphasis on physicochemical properties in drug design
- use of *in silico* ADME models to enable assessment of ADME properties before synthesis
- early incorporation of *in vitro* and *in vivo* ADME studies in drug discovery to identify compounds with optimal preclinical and ultimately clinical ADME attributes as well as potency, selectivity, toxicity, and so on; *in vitro* ADME data should be considered right after identification of hits from the biochemical high throughput screen (HTS) to facilitate identification of chemical series that are easier to optimize
- integration of all preclinical *in vitro* and *in vivo* data to improve the confidence in prediction of the human PK
- exposure–effect modeling with appropriate PD biomarkers in preclinical models to get a quantitative understanding of target and pathway modulation and the anticipated human exposure for sufficient target coverage and, subsequently, efficacy in humans; combination of these data with anticipated human PK will provide the expected efficacious dose
- detailed analysis of clinical PK and PD data to influence design of backup compounds

Interestingly, some have questioned the need for substantial ADME involvement in early drug discovery if the target is both clinically and preclinically unvalidated. Although it is understandable that certain ADME properties [such as reversible or time-dependent cytochrome P450 (CYP) inhibition] do not need to be considered if achieving preclinical proof of concept in an appropriate animal model is the main objective, having sufficient exposure at a reasonable dose will still require substantial involvement of ADME scientists.

In this chapter, a number of strategies have been outlined and examples included to illustrate the importance of ADME in drug discovery. Particular attention has been paid to physicochemical parameters because manipulation of these parameters is something medicinal chemists can relate to easily and, moreover, these parameters have a direct bearing on various ADME attributes. The ultimate goal is to find the right balance of physicochemical properties because some parameters have an orthogonal dependence on physicochemical parameters. For example, a low log *D* value may adversely influence absorption, but a high log *D* value may lead to poor solubility and, hence, poor

absorption and poor metabolic stability. Thus, proper incorporation and balancing of physicochemical parameters will have a positive impact on various ADME parameters and, therefore, increases the probability of success in drug discovery and development, although it does not guarantee it.

3.3 DRUG DESIGN AND THE IMPORTANCE OF PHYSICOCHEMICAL PROPERTIES: IS THERE LIFE BEYOND THE “RULE OF FIVE”?

The first thorough analysis of the impact of physicochemical parameters was performed by Christopher Lipinski at Pfizer in the late 1990s [8]. Lipinski proposed the “rule of five” and he argued that poor absorption is more likely if

- $\log P > 5$
- molecular weight (MW) > 500
- number of hydrogen bond donors (HBDs) > 5
- number of hydrogen bond acceptors (HBAs) > 10

Fortunately, all these parameters can be calculated easily and incorporated in compound design. A recent analysis (Table 3.2) has shown that phase 1 oral drugs have a considerably higher MW and more HBAs and rotatable bonds than marketed oral drugs, which suggests that “rule of five” violations are associated with higher attrition in drug development. The latter has been confirmed by an independent analysis of a large corporate database showing that relatively speaking a higher percentage of compounds with “rule of five” violations attrite for PK reasons (Hop, unpublished data). In addition, an analysis of a database of oral drugs and the ChEMBL database of “hits” indicated that the mean MWs of drugs and “hits” are 333 and 430 Da, respectively, and the mean $\log P$ values are 2.5 and 3.5, respectively [9]. On the other hand, the chemical complexity of oral drugs launched between 1983 and 2002 versus those launched before 1983 has increased with a significant increase in MW and the number of HBAs and rotatable bonds (Table 3.2). The latter is not surprising because the introduction of high throughput screening has increased the emphasis on potency and it has been shown that potency increases with MW and $\log P$ in a statistically significant manner

TABLE 3.2 Average Physicochemical Properties of Oral Drugs in Phase I and Marketed Oral Drugs in Comparison with Lipinski’s “Rule of Five”

	Phase 1 Oral Drugs	Marketed Oral Drugs	Oral Drugs Launched Pre-1983	Oral Drugs Launched 1983–2002	Lipinski’s Rule of Five
Molecular weight (Da)	423	337	331	377	≤ 500
$c\log P$	2.6	2.5	2.3	2.5	≤ 5
$c\log D_{7.4}$	1.3	1.0	—	—	—
Hydrogen bond donors	2.5	2.1	1.8	1.8	≤ 5
Hydrogen bond acceptors	6.4	4.9	3.0	3.7	≤ 10
Rotatable bonds	7.8	5.9	5.0	6.4	—
Rings	—	—	2.6	2.9	—

Source: Data from Wenlock *et al.* [11] and Leeson and Davis [12].

[9]. Nevertheless, the average properties of drugs launched between 1983 and 2002 are well within Lipinski's "rule of five." Analysis of a data set of 108 compounds with clinical data provided by multiple companies corroborates the trend toward greater molecular complexity and lipophilicity with an average MW of 443 Da (range: 171 to 725 Da) and an average log P of 3.75 (range: -5.95 to 12.1) [10]. Unfortunately, it is not known which of these 108 drug candidates—if any—were approved as new drug applications (NDAs).

Most of these analyses refer to clinical candidates nominated before Lipinski's "rule of five" was presented and, therefore, may not reflect current practices and the extent of incorporation of the "rule of five" and associated principles in drug design. Leeson and St-Galley [13] performed a comprehensive analysis of compounds patented by large pharmaceutical companies between 2000 and 2005, and 2006 and 2010, which could potentially reflect the degree of incorporation of the "rule of five" in compound design as it is practiced at this moment. Several interesting conclusions can be drawn.

1. The authors comment on the influence of the "organizational factor" on physicochemical parameters. The differences in clog P and MW across companies are striking with a one log unit difference in clog P between Wyeth (average clog P 4.5) and Pfizer and AstraZeneca (average clog P 3.5) and 60-Da difference in MW between Boehringer Ingelheim (average MW 495 Da) and Pfizer and Vertex (average MW 435 Da). Moreover, large organizational differences in clog P and MW are maintained if only shared targets are taken into consideration. For example, data have been presented for CCR5 antagonists showing a 2 log unit difference in mean log P and 100-Da difference in mean MW between leads from AstraZeneca, GlaxoSmithKline, Merck, and Pfizer [14]. Organizational differences were also obtained for other physicochemical properties such as the number of HBAs and HBDs, the number of rotatable bonds, and the number of sp^3 carbon atoms. An in-house analysis of the physicochemical properties of both the Genentech and Roche compound libraries showed significant differences with the median MW and clog P about 50 Da and close to 0.5 log unit, respectively, higher in the Genentech library than the Roche library. It is likely that the composition of the library has a direct bearing on the properties of the leads and ultimately drug candidates, although fragment-based approaches could have a positive influence, but its full impact may not yet be visible.
2. The mean clog P values decreased for many companies when comparing data from 2000 to 2005 and 2006 to 2010. Statistically significant reductions were noticed for Takeda, Lilly, Schering-Plough, and AstraZeneca. In contrast, the mean MW did not decrease significantly for most companies and even increased for some companies.
3. In agreement with observations by Morphy [15] and Paolini *et al.* [16], significant differences in clog P and MW were observed across targets, but in many cases, the mean values still did not violate the "rule of five." For example, for oral central nervous system (CNS) drugs, the "cutoffs" for parameters such as MW, number of HBAs and rotatable bonds, and polar surface area (PSA) have to be reduced to ensure that the drug can cross the blood–brain barrier [12,17] and this is illustrated in Table 3.3. This chapter focuses on oral drugs, but it is worth noting that different criteria apply for non-oral routes of administration, such as intravenous, topical, and inhaled.

TABLE 3.3 “Pajouhseh’s Rules” for CNS Compounds

Molecular weight (Da)	<450
clog <i>P</i>	<5
Hydrogen bond donors	<3
Hydrogen bond acceptors	<7
Rotatable bonds	<8
PSA (Å ²)	60–90
p <i>K</i> _a	7.5–10.5

Source: Data from Pajouhesh and Lenz [17].

Several companies have confirmed that attrition of compounds breaking the “rule of five” is higher than those abiding by the “rule of five.” Price *et al.* [18] have shown that physicochemical properties are not only important for superior ADME and pharmaceutical properties, there is also a statistically significant relationship with attrition due to toxicity. Specifically, they showed that attrition due to toxicity is about six- to seven-fold higher if clog *P* > 3 and topological polar surface area (TPSA) < 75 Å² versus clog *P* < 3 and TPSA > 75 Å². Although not confirmed, this could be partially due to increased off-target activity of these compounds. Indeed, Gleeson *et al.* [9] have shown that the number of off-target hits increases with increasing log *P* and MW. Alternatively, lipophilic compounds with clog *P* > 3 and TPSA < 75 Å² could be less metabolically stable and (reactive) metabolites could contribute to toxicity.

Although most drug discovery scientists recognize the importance of good physicochemical properties, the degree of incorporation in drug design still varies and many claim that their target (e.g., disruption of protein–protein interaction) necessitates exploration of chemical space beyond traditional drug-like chemical space [19]. Indeed, very successful drugs that violate the “rule of five,” such as atorvastatin, ritonavir, alendronic acid, and montelukast, are used as examples to justify their decisions. Although it is beyond doubt that successful drugs exist beyond the “rule of five,” it is worthwhile to look at the attributes of some of these compounds in relation to their physicochemical properties. An exhaustive analysis is beyond the scope of this chapter, but a more detailed look at several examples from an internal analysis performed in 2006 provides valuable context; the structures of the drugs in question are presented in Fig. 3.2.

3.3.1 Alendronic Acid

Alendronic acid—a synthetic analog of pyrophosphate—has seven HBDs, which is a potential liability. Indeed, absorption is quite low with a bioavailability of about 1% and there is a substantial effect of food and beverages (in particular those rich in multivalent cations such as calcium) on absorption. However, alendronic acid is taken up in the bone—the site of action—and has a half-life of >10 years, which reflects the rate of bone turnover rendering the poor bioavailability less relevant.

3.3.2 Atorvastatin

The MW of the cholesterol-lowering drug atorvastatin is 558.6 Da and this violates the MW “limit” of 500 Da by 12%. The solubility of the calcium salt is very low

Figure 3.2 Structures of drugs referred to in the text.

and the intestinal and hepatic first-pass extraction ratios are high, 0.76 and 0.42, respectively [20]. Not surprisingly, the systemic exposure of the acid form of atorvastatin is relatively low and that may be perceived as a flaw. However, the acid form of atorvastatin is taken up in the liver by organic anion transporting proteins (OATPs) and H^+ -monocarboxylic acid cotransporters—albeit not by design—where it is responsible for most of its dramatic cholesterol-lowering activity. This is nicely illustrated

by Maede *et al.* [21] who administered a microdose of atorvastatin (about 20 mg) to healthy volunteers with or without coadministration of rifampicin (600 mg; an OATP inhibitor) or itraconazole (200 mg; a CYP3A4 inhibitor). The PK plasma area under the curve of atorvastatin increased 12-fold with rifampicin co-administration and stayed the same with itraconazole. In addition, two of atorvastatin's metabolites, 2-hydroxy-atorvastatin and 4-hydroxy-atorvastatin, are active as well. Thus, there is a systemic PK/PD disconnect due to fortuitous hepatic uptake, and neither the relatively low systemic exposure nor the high MW is a liability. Indeed, Lennernäs pointed out that *“The effect of statins is not closely related to the plasma concentration of the drug and its active metabolites. Instead, several reports have shown that the pharmacological response was better correlated with the daily dose of statins”* [20].

3.3.3 Candesartan Cilexetil

Candesartan cilexetil breaks the “rule of five” on several fronts: MW, log *P*, and HBAs. However, candesartan cilexetil is a prodrug by design, and it is completely and rapidly converted to candesartan in the gastrointestinal tract during absorption. Candesartan itself—an angiotensin II receptor antagonist for the treatment of hypertension—is a polar dianionic compound (it contains tetrazole and carboxylic acid functional groups) that would not be absorbed appreciably if it had not been for generation of a prodrug.

3.3.4 Montelukast

Montelukast breaks both the MW and the log *P* rule. The latter is not surprising because the endogenous substrates of the target, the leukotriene D4 (cysLT1) receptor, are very lipophilic as well. However, montelukast has sub-nanomolar potency and this effectively counters, among others, the high plasma protein binding driven by its lipophilicity and being a carboxylic acid.

3.3.5 Orlistat

Orlistat is a reversible covalent lipase inhibitor for weight loss and has a log *P* of 8.6. Not surprisingly, orlistat is practically insoluble in water and the bioavailability is <1%. However, the target is in the intestine and systemic exposure is not required for efficacy.

3.3.6 Ritonavir

Ritonavir is a HIV protease inhibitor and breaks the MW rule by a considerable margin with a MW of 720.9 Da. The log *P*, 4.9, is relatively high as well. Overall, ritonavir has quite undesirable properties and the development was encumbered with significant physical form and formulation issues [22]. Originally, ritonavir was marketed as an oral liquid and a semi-solid capsule. Both formulations contained ethanol to aid solubility because ritonavir is not bioavailable from the solid state. However, after a few years, problems arose because a different conformational polymorph appeared in the production process with even lower solubility and, therefore, greatly reduced bioavailability. This threatened supplies and necessitated immediate reformulation. To solve these issues, the original capsules were replaced with refrigerated gelcaps. Clearly,

the physicochemical properties were a serious liability, but ritonavir was a life-saving treatment for AIDS and the benefits outweighed its distinct disadvantages.

3.3.7 Telmisartan

Telmisartan—another angiotensin II receptor antagonist for the treatment of hypertension—is part of a large group of compounds, which breaks the “rule of five” based on its log *P* value, but the log *D* value is much lower. The log *P* value of telmisartan—a carboxylic acid—is 7.3, but the log *D* value at pH = 7.4 is between 3 and 4. The solubility at neutral pH is relatively low, but the permeability is acceptable and the absolute bioavailability in humans is 43%, which is higher than most other angiotensin II receptor antagonists.

3.3.8 Intrinsic and Extrinsic Attenuating Circumstances

An appropriate term—also used in social sciences—to describe these compounds (3.3.1–3.3.7) is “positive deviants.” This analysis is not meant to be complete, but it does highlight a few valuable points. Many positive deviant drugs that break the “rule of five” are associated with specific attenuating circumstances.

Intrinsic attenuating circumstances:

- The MW rule may be broken because of the presence of a large number of halogen atoms (e.g., amiodarone and levothyroxine). Some argue that the molecular volume is a better measure for absorption than MW and halogen atoms have a disproportionately high atomic weight compared with their volume. This, has resulted in the proposal to calculate the “corrected” atomic weight with fluorine, chlorine, bromine, and iodine counting for 5.2, 19.2, 26.3, and 37.4 Da, respectively, instead of 19.0, 35.5, 79.9, and 126.9 Da, respectively [23].
- Some drugs with a high MW are prodrugs that are cleaved presystemically (e.g., candesartan cilexetil and valganciclovir). Note that several drugs on the market are prodrugs, but not by design (e.g., sibutramine and terfenadine).
- Several acidic and basic drugs break the “rule of five” based on their log *P* value, but the more physiologically relevant log *D* value at the intestinal pH is much lower and compatible with absorption (e.g., gefitinib and telmisartan). Unfortunately, calculation of the log *D* at a specific pH requires calculation of the pK_a , which can be problematic.
- Some drugs with multiple HBDs and HBAs form internal hydrogen bonds, which reduces the number of HBDs and HBAs able to interact with water. See the following sections for more details.

Extrinsic Attenuating Circumstances:

- Some drugs act locally in the gastrointestinal tracts (e.g., miconazole and orlistat).
- Some of drugs that break the “rule of five” display a significant systemic PK/PD mismatch (e.g., alendronic acid and atorvastatin) and the low systemic exposure is not a liability. This determination requires an in-depth knowledge of the biological mechanism and site of action.

- Many drugs that violate the “rule of five” are for life-threatening diseases and the pharmacological benefits outweigh the disadvantages (e.g., ritonavir and saquinavir).

Setting aside the positive deviant drugs described above, the number of compounds that break the “rule of five” without attenuating circumstances and are commercially successful is quite limited and they usually distinguish themselves by being extremely potent (e.g., montelukast). An analysis of drugs that have been launched between 2006 and 2008 comes up with similar conclusions [24]. For example, lapatinib has an MW of 581.1 Da and a $\text{clog } D$ of 6.0. Not surprisingly, the absorption of lapatinib is incomplete and variable and the human daily dose is 1.25 g. However, lapatinib targets a life-threatening disease: breast cancer and other solid tumors. Another example is aliskiren, which is a direct renin inhibitor for primary hypertension. The MW of the free base is 551.8 Da and it has six HBDs and a PSA of $157 \text{ \AA}^2$. Although the solubility of aliskiren is very good, the absolute bioavailability is only 2.6% and the absorbed fraction is estimated to be 5% [25]. In addition, the interindividual variability in human aliskiren PK is large and there is a large, negative food effect [26]; apple juice and orange juice impact the exposure negatively as well [27]. The human PK of aliskiren are governed by a combination of (i) limited passive permeability, (ii) active intestinal efflux mediated by P-glycoprotein (P-gp) and uptake by OATPs, and (iii) a significant hepatic first-pass effect mediated by hepatic uptake and active biliary secretion of the parent compound. However, aliskiren can be detected in the kidney—the site of action—weeks after administration, even though the drug is undetectable in the plasma [24]. Fortuitously, aliskiren accumulates in renin granules, which explains the long-lasting renin angiotensin blockade beyond the half-life of aliskiren [28]. Thus, aliskiren is another classical example of a drug with poor PK driven by specific “rule of five” violations, but a PK/PD disconnect renders the systemic exposure less relevant. These examples and several others led Teague to conclude,

“Where there is a choice in a therapeutic area between a lipophilic agent that violates the rules and one with a better balance of properties, senior management would still be best advised to back the latter. Imperfect agents might simply validate a target and encourage competitors to enter with a drug having the improved properties [24].”

In summary, although differences in physicochemical properties exist across targets (and companies), the majority of existing drugs for most target types follow the “rule of five.” Thus, the conclusion is that extreme physicochemical properties are more likely to be accompanied by poor pharmaceutical and PK properties and, to be a successful drug, other advantageous properties—such as potency, a long off-rate from the receptor, or active distribution to the site of action—have to make up for those deficits and/or the drug should target a life-threatening disease with few therapeutic alternatives. However, as research progresses and more drugs reach the markets, the bar will be raised for drugs targeting very serious disorders as well. A good example is telaprevir (MW is 679.9 Da and the $\log P$ is 4.0), a very promising drug for the treatment of hepatitis C virus (HCV) infection [29]. The bioavailability in preclinical and clinical studies with the initial form was poor (2% or less) and variable. Indeed, scientists from Vertex commented that marble was more soluble than telaprevir. Extensive formulation development was required to come up with a stable amorphous dispersion

with good bioavailability, 20–40%. Despite these heroic and laudable efforts, the dose and the daily pill burden are still remarkably high: 750 mg three times a day. It is likely that in this highly competitive therapeutic area [30], new drugs will appear on the market with a superior regimen and lower cost of goods. Indeed, Merck focused on improving the PK properties and hence the dose in their second generation HCV NS3 protease inhibitor, narlaprevir, which is currently in clinical trials [31]. In conclusion, the nature of the target and its tissue distribution, the therapeutic area, and the competitive landscape—and therefore the target candidate profile—should define *up front* the acceptable physicochemical space and whether potential liabilities associated with breaking the “rule of five” are acceptable or not.

One class of drugs that deserve special recognition is natural products [32]. Despite pronounced “rule of five” violations, many natural products and in particular macrocyclic natural products such as cyclosporine, erythromycin, and tacrolimus display acceptable PK properties, including bioavailability. Several reasons have been proposed for this such as involvement of uptake transporters and extensive internal hydrogen bond formation and reduced conformational flexibility [33]. A recent nuclear magnetic resonance (NMR) and gas phase computational analysis [34] has shown that cyclosporine forms four internal hydrogen bonds, which reduces the number of HBDs from 5 to 1. The internal hydrogen bonds also reduce the effective PSA (not predicted by the TPSA) and lead to a more compact conformation with a lower molecular volume. These factors could explain the remarkably good oral bioavailability of cyclosporine in humans, 30% [34]. Unfortunately, natural product research has been scaled back by most pharmaceutical companies.

Overall, these data reemphasize the importance of physicochemical parameters. However, physicochemical parameters not only influence absorption, they also affect other ADME parameters such as clearance and distribution and the appropriate physicochemical “sweet spot” should be defined for each parameter and each project. This dependence will be illustrated in Section 3.10 after a brief outline of ADME assays deployed in drug discovery to guide design. In addition, in Section 3.10, the dependence of ADME properties on physicochemical parameters will be explored in an *integrated* and *prospective* manner, whereas the relationships highlighted in this section relied mostly on a *retrospective* analysis.

3.4 *IN VITRO* ADME STUDIES

With advances in bioanalysis and the availability of both specific cell lines and subcellular fractions, it has become possible to incorporate a range of *in vitro* ADME end points more effectively in drug discovery with the hope of steering projects towards superior ADME properties. Of course, as will be illustrated below, the ADME properties have to be weighed against other attributes such as potency and selectivity. This has resulted in complex screening cascades incorporating end points that reflect potency, efficacy, selectivity, toxicity, and ADME properties. The following *in vitro* ADME end points are routinely assessed in drug discovery:

- Permeability in Caco-2 or Madin–Darby canine kidney (MDCK) cells or parallel artificial membrane permeability assay (PAMPA)

- Efflux in MDCK or Lilly Laboratories cell-porcine kidney (LLC-PK) cells over-expressing transporters such as P-gp and breast cancer resistance protein (BCRP)
- Metabolic stability in microsomes, S9, cytosol, hepatocytes, or recombinant CYP enzymes
- Reversible CYP inhibition
- Mechanism-based or time-dependent CYP inhibition
- CYP induction
- Plasma protein binding or drug binding in other matrices such as microsomes or brain
- Blood to plasma partitioning

Each of these *in vitro* ADME assays should be incorporated in the overall screening cascade for discovery projects, although the order and extent may vary from project to project. An example of an effective screening cascade for a CNS target is presented in Fig. 3.3.

3.4.1 Permeability

Absorption across the epithelial cell layer in the gastrointestinal tract is the first hurdle a drug has to overcome to reach a systemic site of action. Caco-2 cells, a well-differentiated intestinal cell line derived from human colorectal carcinoma, display many of the morphological and functional properties of the intestinal epithelial cell layer and, consequently, have been used extensively as an *in vitro* model to study absorption. Indeed, a correlation between flux across Caco-2 cells and the fraction absorbed has been established. However, growing these cells is time consuming. Therefore, other cell lines that take less time to grow to confluence, such as MDCK and LLC-PK cells, have been introduced. In these experiments, the bidirectional flux, from apical to basolateral and from basolateral to apical, is determined. If there is asymmetry, this suggests the involvement of uptake or efflux transporters (see below). Non cell-based assays, such as the PAMPA, are used as well. PAMPA employs a barrier made of phospholipids (e.g., phosphatidyl choline and egg lecithin) solubilized in a long-chain hydrocarbon. Despite the experimental convenience of PAMPA, most companies prefer using cell-based assays, because they are a more realistic reflection of the *in vivo* absorption barrier.

3.4.2 Metabolic Stability

Most of the *in vivo* clearance of drugs is driven by metabolism and the most important drug-metabolizing enzymes belong to the cytochrome P450 (CYP) family. The liver is the most prominent site of metabolism and, therefore, hepatocytes and/or hepatic subcellular fractions are used to study metabolism. CYP enzymes and flavin-containing monooxygenases (FMOs) are present on the cytoplasmic side of the endoplasmatic reticulum and as such are active in liver microsomes. Liver microsomes from various species are ubiquitously available and are used in a higher throughput manner to determine the propensity of drugs to be metabolized by CYP enzymes and FMOs. Other enzymes contribute to metabolism as well, but a different subcellular fraction

Figure 3.3 Screening cascade for a CNS target.

may be required. For example, aldehyde oxidases, alcohol dehydrogenases, and aldehyde dehydrogenases are present in cytosol. To get the drug exposed to the full hepatic complement of drug-metabolizing enzymes, including phase 2 enzymes such as uridine diphosphate glucuronosyltransferases (UGTs) and sulfotransferases (SULTs), hepatocytes can be used and the availability of cryopreserved hepatocytes has advanced the field considerably. Thus, it is important to look at different matrices to make sure that specific metabolic pathways are not missed. In the metabolic stability experiments, the compounds are incubated for a short period (20–60 min for microsomes and 1–4 h with

hepatocytes) with appropriate cofactors and the abundance of the parent compound is monitored as a function of the incubation time. Sometimes, the percentage parent compound remaining is reported, but the data are usually converted to a half-life, $t_{1/2}$, and CL_{int} or CL_{hep} values using appropriate scaling factors.

In most cases, microsomes are used as the tier 1 assay with hepatocytes as a downstream, lower capacity tier 2 assay. However, as projects progress and more is known about the metabolic fate of compounds, the cascade can and should be revised accordingly. For example, if direct glucuronidation appears to be the major metabolic pathway, hepatocytes should be used as the tier 1 assay. Metabolism is not limited to the liver and can occur in other organs, such as the intestine, kidneys, and lungs, as well. Microsomes of those tissues are commercially available. Usually, most attention is paid to metabolism in the liver, but if it becomes clear that hepatic metabolism cannot explain the observed *in vivo* clearance, other tissue should be considered and microsomes of those tissues can be incorporated in screening cascades.

3.4.3 Phenotyping

To better understand the human PK and to assess the likelihood of a compound being the “victim” of a drug–drug interaction, it is important to identify the individual enzymes responsible for the metabolism of a compound. This is commonly done for CYP and/or UGT enzymes. The experiments involve incubating the compound with recombinant enzymes or incubating the compound with microsomes and using specific antibodies or chemical inhibitors.

3.4.4 Drug–Drug Interaction

Several drugs, such as cerivastatin, cisapride, terfenadine, and mibefradil, have been withdrawn because of severe drug–drug interaction, and therefore, this should be addressed early on in the screening cascade. The most ubiquitous drug–drug interactions are the result of inhibition of CYP enzymes. Reversible CYP inhibition can be determined by looking at the inhibition of metabolism of probe substrates to specific metabolites mediated exclusively by a specific CYP enzyme. Examples of commonly used probe substrates are provided in Table 3.4.

If throughput is an issue, the percent inhibition of turnover of the probe substrates at a specific concentration of the drug candidates can be determined. Alternatively, multiple concentrations of the drug candidates can be used and an IC_{50} value can be determined. The IC_{50} value provides value information to assess the risk of a clinical drug–drug interaction, but quantitative predictions also require information about the anticipated exposure of the “perpetrator” and the fraction of the “victim” drug being metabolized by the inhibited CYP.

Mechanism-based CYP inhibition should be explored as well, because it inactivates the enzyme either in a covalent manner (heme or apoprotein adduct formation) or via metabolite–intermediate complex formation and requires *de novo* synthesis of the enzyme. Indeed, many of the most pronounced drug–drug interactions are due to mechanism-based CYP inhibition [35] and it is remarkably prevalent these days; an analysis by Zimmerlin *et al.* [36] indicated that 4% of 400 marketed drugs were positive, whereas 23% of 4000 randomly selected new chemical entities from Novartis

TABLE 3.4 Probe Substrates and LC-MS/MS Detection Method Used for Inhibition of Specific Cytochrome P450 Enzymes

Enzyme	Reaction	Ionization Mode	MRM Transition
CYP1A2	Phenacetin- <i>O</i> -deethylation	+	152 → 110
CYP2B6	Bupropion hydroxylation	+	256 → 238, 139
CYP2C8	Paclitaxel-6 α -hydroxylation	+	870 → 286, 105
CYP2C9	<i>S</i> -Warfarin-7'-hydroxylation	+	325 → 179
CYP2C9	<i>S</i> -Warfarin-7'-hydroxylation	—	323 → 177
CYP2C9	Tolbutamide-4'-hydroxylation	+	287 → 171, 89
CYP2C9	Tolbutamide-4'-hydroxylation	—	285 → 186
CYP2C19	<i>S</i> -Mephenytoin-4'-hydroxylation	+	235 → 150
CYP2C19	<i>S</i> -Mephenytoin-4'-hydroxylation	—	233 → 190
CYP2D6	Dextrometorphan- <i>O</i> -demethylation	+	258 → 199, 157
CYP2E1	Chlorzoxazone-6-hydroxylation	+	186 → 130
CYP2E1	Chlorzoxazone-6-hydroxylation	—	184 → 120
CYP3A4/5	Midazolam-1'-hydroxylation	+	342 → 324, 297, 203
CYP3A4/5	Testosterone-6 β -hydroxylation	+	305 → 269

drug discovery projects were positive. Mechanism-based inhibition is characterized by the following:

- NADPH-dependent inactivation;
- concentration-dependent inactivation;
- time-dependent inactivation;
- enzyme activity not restored by dialysis;
- inactivation rate diminished in the presence of competing substrate;
- spectral shift from 450 nm.

The most common assay format involves preincubation of the drug candidate in microsomes followed by dilution and incubation with an appropriate probe substrate (Table 3.4). The preincubation may give rise to a marked decrease in activity of the CYP enzyme and, hence, reduced turnover of the probe substrate specific for that enzyme. Because the experiment is carried out in a time-dependent manner, this phenomenon is usually called *time-dependent inhibition* (TDI), but it is important to realize that the observed inhibition can be due to both mechanism-based inhibition and the formation of metabolites that are potent CYP inhibitors. To increase throughput, the experiment can be performed with a single preincubation period (usually 30 min) with multiple concentrations of the investigative drug in the absence and presence of NADPH. The extent of TDI is reflected by the shift in the IC₅₀ value, hence the name “IC₅₀ shift assay” [37]. To enable clinical prediction, multiple concentrations and multiple preincubation times are desirable, and K_I and k_{inact} values can be obtained after mathematical transformation of the data. As explained for reversible CYP inhibition, quantitative predictions also require information about the anticipated exposure of the “perpetrator” and the fraction of the “victim” drug being metabolized by the inhibited CYP.

Both reversible and mechanism-based CYP inhibition have been performed in hepatocytes, but the use of microsomes is most ubiquitous.

3.4.5 CYP Induction

CYP induction assays are usually not tier 1 assays in drug discovery projects because the prevalence of induction is limited. However, for certain classes of drugs, induction is quite common. The gold standard assay is incubation of the drug candidates with multiple batches of fresh hepatocytes for 24–48 h. After removal of the supernatant and washing of the cells, the hepatocytes are incubated with specific probe substrates (Table 3.4) to determine via functional activity if the expression of specific CYP enzymes is up-regulated. Alternatively, mRNA expression can be monitored. Cell viability should be monitored as well, because it could circumvent detection of CYP induction. This is clearly a low throughput assay and for projects with specific induction issues pregnane X receptor (PXR) binding is usually employed to enable sufficient throughput and an adequate turnaround time.

3.4.6 Plasma Protein Binding and Tissue Binding

Knowing the non-covalent binding of a drug to plasma proteins or lipids in tissue is important because the free concentration is the presumed driver of efficacy (the “free drug hypothesis” or “free drug concept”) [38,39]. However, it is not a parameter that should be “optimized” (see below). In plasma, most drugs bind extensively to plasma proteins such as albumin (neutral compounds and acids) and α -acid glycoprotein (basic compounds). In tissues, binding is much less specific and mainly reflects affinity for interaction with phospholipids. Several assays are available to determine the free or unbound drug concentration. Ultrafiltration and ultracentrifugation are used, but the gold standard is considered to be dialysis. Dialysis can be performed with individual tubes or using a 96-well block with buffer on one side and plasma or tissue homogenate on the other side. After incubation, both sides are sampled. If binding is high (plasma protein binding in excess of 99% is not uncommon for higher MW and/or lipophilic drugs), a very sensitive LC-MS/MS assay has to be used. For proper PK/PD modeling, it is important to know the free tissue concentration at the site of action and this can be obtained by multiplying the total concentration and the free fraction in the relevant tissue. In the absence of the involvement of uptake or efflux transporters, the free drug concentration in plasma and tissue should be the same, although the free fraction in plasma and tissue, and hence the total drug concentration in plasma and tissue, may be quite different.

3.4.7 Drug Transport Assays

Studying drug transport has become more common because many drugs are to some extent substrates or inhibitors of uptake or efflux transporters [40]. The most extensively studied drug transporter is P-gp (also called *MDR1*) because it can (i) limit intestinal absorption, (ii) enhance biliary excretion, and (iii) limit brain and/or tumor penetration. Thus, for central targets requiring sufficient brain exposure, it is essential to incorporate a P-gp assay early on in the screening cascade. Efflux in Caco-2 or MDCK cells may be indicative of the compound being a P-gp substrate, but the evidence is not conclusive until confirmed by efflux reduction with a specific P-gp inhibitor. A more common assay involves cells overexpressing P-gp. Cell lines for other transporters such as BCRP, OATs, OCTs, OATPs, and MRPs are available as well, but are usually not used

extensively in drug discovery, because they do not seem to play a major role in drug disposition with the exception of specific classes of drugs (such as hepatic uptake of statins via OATPs).

Many pharmaceutical companies have higher throughput ADME screening facilities for these assays (3.4.1–3.4.7). The assays are heavily automated and use 96- or 384-well format [41,42]. The end points usually involve sample analysis via LC-MS/MS. A capacity of 200–1500 compounds per week through the tier 1 assays (usually metabolic stability in microsomes and reversible CYP inhibition) is not uncommon [43]. Although these data can and should be used to influence design in drug discovery, they are not rigorous enough for regulatory submissions and more customized assays are required for that purpose.

3.5 *IN VIVO* PHARMACOKINETIC STUDIES

In vivo PK studies continue to play an important role in drug discovery and development. The purpose of these studies is threefold:

- determination of exposure in preclinical species to inform subsequent PD or efficacy studies
- determination of exposure in preclinical species to aid in the interpretation of toxicology studies
- determination of PK parameters in preclinical species to aid in the identification of compounds with appropriate human PK.

The availability of sensitive and selective mass spectrometers interfaced with LC systems has greatly facilitated the incorporation of *in vivo* PK studies in drug discovery. In most cases, exposure in plasma is measured, but other matrices such as blood, urine, feces, or specific tissues of pharmacological or toxicological interest may be sampled as well. Some companies rely heavily on *in vivo* PK data in their screening cascades necessitating higher throughput approaches. The most common approaches are the following.

3.5.1 Cassette or “n-in-one” Dosing

A mixture of drugs is administered to the same animal resulting in a significant reduction in the number of animals used for PK studies. With the advent of highly selective and sensitive triple quadrupole mass spectrometers operating in the multiple reaction monitoring (MRM) mode (Fig. 3.4), it is feasible to determine the exposures of all drugs in the cassette [44,45]. Nevertheless, it is important to select the drug candidates in the cassette such that common metabolic pathways do not interfere with the detection of the parent compounds. For example, drug candidates that differ in MW by 16 or 32 Da should be avoided. Drug–drug interaction via inhibition of CYPs or other metabolic enzymes is not inconceivable either [46]. However, this would generally result in a higher exposure and these “false positive” compounds would be captured in subsequent experiments. Thus, the risk of “false negatives” (i.e., compounds with lower exposure in a cassette than as a single agent) is low. Nevertheless, the dose is usually lowered in cassette studies to reduce the risk of drug–drug interaction. In

Triple Quadrupole Scan Modes					
	Ionization		Fragmentation		Detection
Product ion spectrum	ABC ⁺	→	A ⁺ + BC	→	A ⁺
			AB + C ⁺		C ⁺
	ABD ⁺	→	A ⁺ + BD	→	A ⁺
			AB + D ⁺		D ⁺
Precursor ion spectrum	ABC ⁺	→	A ⁺ + BC	→	A ⁺
			AB + C ⁺		A ⁺
	ABD ⁺	→	A ⁺ + BD	→	A ⁺
			AB + D ⁺		A ⁺
Constant neutral loss spectrum	ABC ⁺	→	A ⁺ + BC	→	C ⁺
			AB + C ⁺		C ⁺
	ABD ⁺	→	A ⁺ + BD	→	D ⁺
			AB + D ⁺		D ⁺

Figure 3.4 Principles of the product ion, precursor ion, and constant neutral scan modes feasible with a triple quadrupole mass spectrometer.

addition, a reference compound with well-established PK and a close analog of the drug candidates under investigation is usually included in every cassette. Generally, the substantial increase in output outweighs the (manageable) risks.

3.5.2 Sample Pooling

To avoid the complications associated with cassette dosing as described above, some companies employ sample pooling. In this approach, individual compounds are dosed and plasma samples are subsequently pooled and analyzed with a triple quadrupole mass spectrometer (e.g., cassette-accelerated rapid rat screen [47]). This technique eliminates the risk of PK drug–drug interaction, but the risk of bioanalytical interference due to metabolites remains.

In addition, equipment such as automated blood sampling, multiplexing, and column switching with staggered parallel analysis is routinely used to enable higher throughput for *in vivo* PK studies. Although MRM on a triple quadrupole mass spectrometer is the mainstay in bioanalysis, there is a recent push to use high resolution MS [48]. The data are gathered with a single stage of mass analysis, which would result in a loss of selectivity, but the high resolution makes up for that. Moreover, it is now possible to monitor both the parent compound and metabolites without prior knowledge about the nature of the metabolites.

3.6 TISSUE DISTRIBUTION

Knowledge of tissue distribution can be valuable to relate to efficacy or toxicity in a particular tissue. Some compounds are taken up in tissues and are present in much higher concentrations than in plasma either due to uptake transporters, preferential binding to cellular components (e.g., lipids or melanin), or pH-mediated trapping of the charged form of the drug (e.g., lysosomal trapping). Alternatively, there can be

active efflux of drug candidates out of tissues such as the brain. The latter can be either desirable (e.g., limited brain penetration of cytotoxic oncology drugs that target non-CNS tumors) or undesirable (e.g., limited brain penetration for CNS agents). A comprehensive view of tissue distribution can be obtained by quantitative whole body autoradiography (QWBA), but this requires radiolabeled material, which is usually not available in drug discovery. Moreover, QWBA cannot distinguish the parent compound from metabolites. A more convenient, but time-consuming, approach is excision of individual tissues, followed by homogenization and quantitation by LC-MS/MS. This technique does not require radiolabeled material and is very sensitive; the MRM mode prevents significant interference by endogenous components. However, each tissue must be examined separately and the distribution within each tissue is lost.

Imaging via matrix-assisted laser desorption/ionization (MALDI) was introduced in the early twenty-first century and it has been successfully used to detect drugs and their metabolites in tissues [49]. Tissue or whole body slices are obtained in the same manner as for QWBA, but the slices are subsequently coated with a finely dispersed matrix solution (such as sinapinic acid in methanol). The solvent solution extracts the analytes out of the tissue and the matrix itself allows ionization after irradiation with a laser. In most cases, detection in the MS/MS mode is preferred to prevent interference by the abundant matrix ions. The tissue distribution of either the parent drug and/or its metabolites is obtained by scanning the laser across the tissue with a spatial resolution of about 50 μm . Although significant progress has been made, this technique still suffers from limited sensitivity and lengthy data acquisition. The latter can be addressed by acquiring data in the MS mode with a high resolution mass spectrometer and extracting the images for the parent drug and its metabolites post-acquisition [50].

3.7 METABOLITE IDENTIFICATION

LC-MS/MS is a very powerful tool for metabolite identification. Metabolites generated from *in vitro* incubations or *in vivo* studies can be detected with relative ease and this information can be communicated to medicinal chemists to address specific metabolic liabilities in the next generation of compounds. Several mass spectrometric scan modes are available to aid in the assignment of structures of metabolites (Fig. 3.4). The most common scan modes are as follows:

- *Product Ion Scan.* A protonated or deprotonated metabolite is selected with the first mass analyzer and subsequently fragmented by collision with an inert gas. Finally, the fragments are analyzed according to their mass or, to be precise, their mass-to-charge (m/z) ratio in the second mass analyzer.
- *Constant Neutral Loss Scan.* In this scan mode, the first and second mass analyzers are scanned with a fixed offset that corresponds to a common fragment lost from the parent drug and/or its metabolites in the collision cell. For example, glucuronide metabolites can be detected by performing a 176-Da constant neutral loss scan in the positive ion mode and glutathione adducts can be detected with a 129-Da constant neutral loss scan.
- *Precursor Ion Scan.* A precursor ion scan allows monitoring of ions (corresponding with the parent drug and/or its metabolites) that generate a common fragment ion. In this scan mode, the first mass analyzer is scanned and the second mass

analyzer is held constant at the mass-to-charge ratio of the common fragment ion. For example, glutathione adducts can be detected by a m/z 272 precursor ion scan in the negative ion mode [51].

Note that not all scan modes are available on all types of mass spectrometers due to design limitations. However, the most common type of mass spectrometer, the triple quadrupole instrument, allows all three of these scan modes. With the availability of high resolution time-of-flight, orbitrap, and Fourier-transform mass spectrometers, it is possible to obtain accurate mass values in either the MS or the MS/MS modes, which greatly facilitates interpretation of spectra and assignment of metabolite structures. In the MS mode, an accurate mass provides—with a reasonable degree of confidence—the molecular formula of the metabolite and thereby the type of biotransformation involved. In the MS/MS mode, accurate mass values of the fragment ions facilitate interpretation of the MS/MS spectrum and, consequently, assignment of the structure of the metabolite. An additional feature of a high resolution mass spectrometer is the ability to apply a mass defect filter to the data file to remove endogenous matrix-related ions [52,53]. The mass defect refers to the fractional mass of the parent compound and its metabolites obtained using the accurate mass for each atom. For example, the exact mass of atorvastatin is 558.2521 Da and the corresponding mass defect is 0.2521 Da. Metabolites with minimal structural changes relative to the parent compound (i.e., +O, +2O, and -CH₂) can be detected with a mass defect filter similar to that used for the parent compound because the change in fractional mass is minimal (-0.0051, -0.0102, and -0.0156 Da for +O, +2O, and -CH₂, respectively). For conjugates such as sulfates or glucuronides, the mass defect filter should reflect the change in the fractional mass of the conjugates.

Despite these advances in the field of MS, it is still very hard to identify the exact site of metabolism, in particular for the most common metabolic process: aliphatic and aromatic hydroxylation. Identification is usually limited to determination of the moiety of the molecule that was metabolically transformed and a Markush structure of the metabolite is obtained. Sometimes, the exact site of metabolism may be unambiguous (e.g., for simple N-dealkylations), but for common pathways, such as oxidation, it is frequently required to isolate the metabolite and obtain NMR data to identify the exact structure. Additional tools available to facilitate metabolite identification are as follows:

- isotope patterns of $[M + H]^+$ or $[M - H]^-$ ions; metabolite identification is greatly facilitated by the presence of atoms with a unique isotope pattern such as chlorine and bromine;
- presence of a radiolabel (usually ³H or ¹⁴C);
- chemical derivatization;
- hydrogen–deuterium exchange [54];
- studies with close in analogs.

More recently, it has been advocated to integrate quantitative bioanalysis and metabolite identification in one experiment. This can most easily be achieved using a high resolution instrument operating in the MS mode [48]. The high resolution ensures appropriate selectivity for detection and quantitation of the parent compound.

In addition, the data can be interrogated for the presence of metabolites and the accurate mass measurement can provide the molecular formula of the metabolite. A subsequent experiment may be required to obtain structural information via product ion scans. Alternatively, the instrument can automatically switch from MS to MS/MS mode (provided it has this capability) in a data-dependent manner. It remains to be seen whether the quality of the quantitative information is sacrificed.

Another area of metabolite identification that is receiving more and more attention is the detection of adducts that are indicative of bioactivation [55,56]. Many drugs are bioactivated and there is some (mostly circumstantial) evidence that reactive intermediates may give rise to (idiosyncratic) toxicity. Although the reactive intermediates cannot be detected, it is possible to trap them with agents such as glutathione (abundant in the liver and an effective nucleophile by virtue of its cysteine sulfhydryl group), potassium cyanide (a “hard” nucleophile for detection of iminium species), and methoxylamine and semicarbazide (to detect aldehydes). LC-MS/MS assays have been implemented to facilitate detection of these adducts. For example, glutathione adducts can be detected by a 129-Da neutral loss scan in the positive ion mode or a m/z 272 precursor ion scan in the negative ion mode [51]. Some labs have taken this a step further and are examining covalent binding to cellular components (usually proteins). Nakayama *et al.* [57] looked at the correlation between covalent binding and glutathione adduct formation and TDI using a data set of 42 structurally diverse compounds. First, they found no statistically significant correlation between the formation rate of glutathione adduct formation and the extent of covalent binding; several compounds, including pioglitazone and ritonavir, showed extensive covalent binding (>50 pmol/min/mg protein as defined by Evans *et al.* [55]). It would be interesting to see whether a correlation would have appeared if other trapping agents, such as cyanide and methoxylamine, would have been incorporated in the assay. Second, there was no statistically significant relationship between the enzyme inactivation rate (as assessed by the TDI assay) and the extent of covalent binding. Third, the authors calculated the intrinsic clearance for forming reactive metabolites by summing (i) the intrinsic clearance for forming reactive metabolites based on the formation rate of glutathione adducts and (ii) the intrinsic clearance for forming reactive metabolites based on the enzyme inactivation rate in the TDI assay. Fortunately, there was a statistically significant correlation between the intrinsic clearance for forming reactive metabolites as defined above and the extent of covalent binding with no obvious false negatives (clean in the TDI assay and/or glutathione trapping assay, but more than 50 pmol/min/mg protein in the covalent binding assay). Thus, this suggests that the combination of the TDI and the glutathione trapping assays can serve as a surrogate to assess the risk for covalent binding. Many scientists have advocated the use of covalent binding as a surrogate for toxicity, but it has been shown that there is no clear relationship between the extent of covalent binding and hepatotoxicity [58]. Moreover, it requires radiolabeled material and, therefore, is not very practical in drug discovery. A most interesting finding in the analysis of Nakayama *et al.* [57] is that atorvastatin was determined to have covalent binding of 352 pmol/min/mg protein, which far exceeds the guideline of 50 pmole/min/mg protein [55]. Nevertheless, atorvastatin is remarkably safe and commercially successful and the low dose, 10–80 mg, may be the main reason for this. It has been well established that the vast majority of drugs withdrawn from the market due to idiosyncratic adverse drug reactions (IADRs) or having a black box warning due to IADRs have a dose of >100 mg [59].

In conclusion, the degree of concern about formation of reactive metabolites should be guided by the following parameters:

- clinical dose and exposure;
- duration of therapy (short vs long duration);
- therapeutic area (life threatening or not?);
- target population (young vs old, healthy vs diseased);
- first in disease/class or not;
- lead compound versus backup;
- species differences (bioactivation may be unique to one species).

3.8 IN SILICO ADME MODELING

A substantial benefit from higher throughput *in vitro* ADME screening is that there is now a wealth of data available that can be used to build sophisticated *in silico* ADME models. *In silico* models have been available for years and some of them are commercially available. However, most of the commercially available models are of limited value because the chemical diversity of the data used to build the model is limited in size and, sometimes, the data were obtained from the literature using different experimental protocols. High throughput ADME screening—generating in excess of 10,000 data points per year—has overcome these hurdles and, consequently, models have been built for most *in vitro* ADME endpoints: permeability, metabolic stability in microsomes and hepatocytes, microsomal binding, plasma protein binding, reversible and time-dependent CYP inhibition, and so on. [60]. Although global models are useful, in some cases, it may be better to build a local model that better defines the chemical space of interest. The models involve a range of chemical descriptors and/or the structures of the compounds in the training set. Different statistical methods (regression methods: partial least squares; Bayesian methods; supervised learning methods: decision trees, support vector machine; and neural networks) can be used as well. The output of the model can either be categorical or numerical. Besides the output, the confidence in the prediction is a critical parameter. The confidence in the prediction is usually derived from (i) the structural similarity of the compound under investigation with those in the training set and (ii) the number of structurally similar compounds (nearest neighbors). This, combined with an objective validation of the model using compounds not in the training set, guides the ultimate use and incorporation of the model in drug discovery. For example, Lee *et al.* [61] built an *in silico* model for metabolic stability in microsomes and showed that 72% of the compounds without close nearest neighbors were predicted correctly, whereas 88% of the compounds with more than 33 nearest neighbors were predicted correctly. The same phenomenon is also apparent from the data in Fig. 3.5 showing the correlation between the *in silico* and *in vitro* human liver microsomal extraction ratio. The color of the symbols characterizes the similarity with the compounds in the training set and the shape of the symbols reflects the number of nearest neighbors in the training set. Generally, the dark gray squares in Fig. 3.5 (similarity score ≤ 0.7 ; number of nearest neighbors ≤ 7.8) reflect compounds with less similarity and fewer nearest neighbors and, not surprisingly, the predictions are less

Figure 3.5 Extraction ratio (ER) measured in human liver microsomes (HLM) versus the calculated ER in HLMs derived from an *in silico* metabolic stability model. The color of the symbol is indicative of the similarity (Sim) and the shape is indicative of the number of nearest neighbors (NN). (See color insert.)

accurate. It is important that the data set to build the *in silico* models is regularly updated to reflect the evolving chemical space.

Although models serve a very useful purpose, most models are generally not meant to replace experimental data—or at least not at this stage. The main goal should be to increase the *probability* of identifying compounds with optimum properties, such as metabolic stability or permeability, and to identify the SAR of the ADME properties. Indeed, the models can be used to triage compounds *before* synthesis and speed up the lead optimization process. In-house data at Genentech show that the number of compounds with good microsomal stability (CL_{hep} in human liver microsomes $< 6.2 \text{ mL/min/kg}$) increased from $< 10\%$ of all new compounds synthesized to slightly more than 20% after implementation of an *in silico* metabolic stability model in 2010, but without dramatic changes in the portfolio. Of course, there are many reasons to synthesize particular compounds and if there is a good design hypothesis (e.g., based on specific interactions with the target derived from the crystal structure or a homology model), synthesis should proceed despite unfavorable ADME predictions. Ideally, multiple *in silico* models, including potency models, are available and used in a parallel manner to triage very large virtual libraries. Unfortunately, the progress with building reliable *in silico* models for potency appears to lag behind the advances with *in silico* ADME models. The *in silico* ADME model can also be used to triage compounds already synthesized before submission to *in vitro* ADME assays if the capacity of the assays is limited. For example, if the model is highly confident that a particular compound is metabolically unstable, there is no reason to submit it for experimental verification.

Figure 3.6 (a) Relationship between solubility index (sum of the log P and the number of aromatic rings) and the metabolic stability in human liver microsomes. The following definitions for metabolic stability are used: stable $CL_{hep} < 6.2$ mL/min/kg (gray), intermediate $6.2 \text{ mL/min/kg} < CL_{hep} < 15$ mL/min/kg (light gray), and unstable $CL_{hep} < 15$ mL/min/kg (dark gray). (b) Relationship between the predicted probability of being stable in the human liver microsomes metabolic stability *in silico* model (0, infinitely small probability of being stable; 1, highest probability of being stable) and the measured metabolic stability as a function of the solubility index. (None of the compounds examined here were in the training set of the model.) The definitions are the same as in (a). (See color insert.)

The value of *in silico* models is also illustrated by the data in Fig. 3.6. Figure 3.6 shows the predicted and experimental human liver microsomal metabolic stability data of more than 2600 compounds not in the training set as a function of the solubility index. The *in silico* metabolic stability model is built with a training set of *in vitro* data from close to 20,000 diverse compounds obtained under consistent experimental conditions. The solubility index is the sum of the log P and the number of aromatic

rings and the combination of these two parameters is a reasonably reliable indicator of the experimental solubility and can be routinely calculated [62,63]. A solubility index of 7 or more indicates a high *likelihood* of very low solubility, $\leq 1 \mu M$, and a solubility index of 5 or less is usually desirable. First, the experimental data in Fig. 3.6a show that compounds with a solubility index of <5 have a 3.5-fold greater probability of being *in vitro* metabolically stable than compounds with a solubility index of 7 or more (38% vs 11%). The latter probably reflect the increased likelihood of large lipophilic compounds with many aromatic rings to be both poorly soluble and extensively metabolized. Second, Fig. 3.6b shows that the ability of the *in silico* metabolic stability model to identify compounds that are experimentally stable in human liver microsomes is better for compounds with a low solubility index. For compounds that have a predicted probability of being stable >0.8 (0 = infinitely small probability of being stable; 1 = highest probability of being stable) close to 60% are indeed metabolically stable if the solubility index is <5 , whereas about 40% are experimentally stable if the solubility index is more than 7. Thus, both the solubility index and the *in silico* metabolic stability model can serve as a tier 0 screen to improve the *probability* of identifying compounds with better PK and pharmaceutical properties.

The output of an *in silico* CYP3A4 time-dependent CYP inhibition model is presented in Fig. 3.7. The TDI model is based on a training set of close to 2000 compounds with midazolam or testosterone as the probe substrates of 3A4 and using an “IC₅₀

Figure 3.7 Relationship between the predicted probability of displaying time-dependent inhibition (TDI) of CYP3A4 using an in-house *in silico* model (0, very low probability for TDI; 1, high probability for TDI) and the measured extent of TDI using an “IC₅₀ shift” protocol with the fold-change in area under the percent activity remaining versus inhibitor concentration curve (i.e., AUC change) rather than the traditional fold-change in IC₅₀ value as the experimental endpoint to determine the magnitude of TDI [64]. (None of the compounds examined here were in the training set of the model.) The following definitions for TDI are used: low risk $< 15\%$ AUC change (light gray), intermediate risk between 15% and 30% AUC change (white), and high risk $> 30\%$ AUC change (dark gray).

shift” protocol with the fold-change in area under the percent activity remaining versus inhibitor concentration curve rather than the traditional fold-change in IC_{50} value as the experimental endpoint to determine the magnitude of TDI [64]. The output of the model is the probability of showing TDI with 1 representing a very high probability for TDI and 0 a very low probability. Although using hard “cutoff” values is not advisable, a probability of 0.7 or more indicates a high probability of displaying TDI, whereas below 0.4 the risk is much lower. Nevertheless, there is a finite probability for both “false negatives” and “false positives”—as is the case for any *in silico* model despite an effort to minimize them while building the model. “False negatives” are of limited concerns because compound synthesis will proceed and the experimental data will ultimately supersede the *in silico* data. “False positives” may greatly concern project teams because those compounds may be dropped from further pursuit. Although that may be alarming, other compounds that are presumably predicted to display superior properties are synthesized instead. Thus, the detrimental impact may be minimal and the overall positive impact of incorporating *in silico* models far outweighs this risk.

As mentioned before, some models are commercially available and models such as MetaSite and StarDrop have proven to be relatively reliable. Although the underlying computational algorithms are different for MetaSite and StarDrop, both are capable of predicting the site of metabolism considering both the intrinsic reactivity of each potential site to oxidative metabolism by CYP enzymes as well as the accessibility of the site of metabolism to the active oxy-heme species in the CYP enzymes. Using the literature and in-house compounds, it was shown that both MetaSite and StarDrop are capable of predicting the right site of metabolism about 60–90% of the time for CYP2C9, CYP2D6, and CYP3A4 [65]. Note that both software packages predict the site of metabolism, but not the exact metabolic pathway nor the rate of metabolism. An example of the use of MetaSite is presented in Fig. 3.8 (only partial structures are shown because the structures are still proprietary). A potent compound was identified, but its clearance in mice was very high, 157 mL/min/kg. MetaSite predicted the site of metabolism as the 4-position of the piperidine ring. Next, a compound was synthesized with a substituent at the 4-position and the clearance was much lower, 8.6 mL/min/kg, and the free fraction in plasma was slightly increased as well. Subsequent metabolite identification efforts with the first compound indicated that the piperidine ring was indeed the site of metabolism. Unfortunately, the potency of the second compounds was more than 1000-fold lower.

There is another inherent and implied advantage of using *in silico* ADME models and that is that it enables evaluation of hits from the HTS screen. In the past, the

Figure 3.8 MetaSite prediction of the site of metabolism for a high clearance compound inspiring chemical modification that resulted in a low clearance compound.

decision to pursue a certain chemical series was based on its potency and chemical intuition. However, it has been shown that different medicinal chemists view attractiveness of a compound or series remarkably different [66]. The *in silico* ADME models allow early incorporation of appropriate ADME parameters and have them weighted as important as endpoints such as potency and selectivity. This may be particularly important because on many occasions, it is easier to optimize potency and selectivity than ADME properties. Thus, early and appropriate incorporation of *in silico* ADME models followed closely by experimental verification will facilitate identification of drugable chemical space and subsequently speed up lead optimization.

3.9 MULTIPARAMETER OPTIMIZATION

Currently, the lead optimization process is much more complex than it was even 10 years ago because the sheer quantity of parameters and data has grown almost exponentially. The ability of a human, even an experienced drug “hunter,” to optimize more than three parameters in a simultaneous manner is severely limited. Thus, computational tools are available that allow the user to incorporate multiple parameters and rank order the compounds. A simple model resembling a traffic light that can be used to assess absorption in the gastrointestinal tract is presented in Table 3.5 [23] and incorporates solubility, lipophilicity, the corrected MW (see above), PSA, and the number of rotatable bonds. The “cutoff” values for each property are presented in Table 3.5 and the overall score is a summation of those for the individual parameters with a score of 0 being ideal and 12 being highly undesirable. An analysis showed that 70% of the oral drugs have an overall score of 2 or less, whereas HTS hits from 20 screens showed a Gaussian-like distribution peaking at a score of 5. Additional parameters can be incorporated easily and these parameters can be either computational or experimental in origin.

Another example is the model used to assess whether a compound is likely to be able to cross the blood–brain barrier [67]. The parameters included are $\text{clog } P$, $\text{clog } D$, MW, TPSA, number of HBDs, and $\text{p}K_a$. Each parameter has a desirable and less desirable range and a transition resulting in a score of 0–1 with 1 being most desirable. Subsequently, the individual scores for the six parameters are summed with 6 being the highest possible score. Most CNS drugs have a score of 4 or more. Not surprisingly, experimental verification indicates that a high score is accompanied by a high passive permeability (P_{app} value in MDCK cells), low P-gp liability (efflux ratio

TABLE 3.5 Traffic Light Multiparameter Optimization Tool

Traffic Light Color	Traffic Light Value	Solubility (mg/L)	$\text{clog } P$	Corrected Molecular Weight	PSA ($\text{\AA}^2$)	Rotatable Bonds
Green	0	≥ 50	≤ 3	≤ 400	≤ 120	≤ 7
Yellow	1	10–50	3–5	400–500	120–140	8–10
Red	2	< 10	> 5	> 500	> 140	≥ 11

Source: Data from Lobell *et al.* [23].

in P-gp overexpressing MDCK cells), and low unbound intrinsic clearance ($CL_{int,u}$ in human liver microsomes).

The two examples described above were focused on physicochemical parameters and each input parameter had the same weight. It is also possible to include a range of experimental data and more sophisticated tools allow the user to adjust the weight of each parameter and to incorporate experimental uncertainty [68].

Human dose predictions in early drug discovery (in contrast to dose predictions performed during candidate nomination, which are based on more sophisticated human PK prediction and PK/PD analysis) is another form of multiparameter optimization, although it may not be perceived by many as such. For example, the dose can be predicted with Equation 3.1 using the following parameters:

$C_{ss, avg}$, cellular potency IC_{50} value;

CL , human clearance derived from human liver microsomes or hepatocytes or rat–human scaling;

τ , dosing interval (usually 12 or 24 h);

F , back-calculated bioavailability assuming that the clearance is solely hepatic ($1 - CL/Q$) or based on preclinical bioavailability data.

$$\text{Dose} = \frac{C_{ss, avg} \cdot CL \cdot \tau}{F} \quad (3.1)$$

It is important to emphasize that this is not meant to be an accurate dose prediction. It is merely meant to provide an indication about the order of magnitude and it can be used to categorize compounds/chemical series.

A more comprehensive overview of multiparameter optimization in drug discovery is presented in Ref. 69.

3.10 INCORPORATION OF ADME DATA IN DRUG DISCOVERY TO IMPROVE PHARMACOKINETICS

Incorporation of all relevant parameters in drug discovery in a *prospective* effort to find a drug with the “perfect” balance of properties is extremely challenging and time consuming and frequently it is necessary to compromise. Indeed, “... *the level of in vitro potency of a lead for its intended target(s) is the key parameter at the beginning of a drug discovery program. This idea is extended further in lead generation-optimization based on the assumption that the most potent molecules in vitro are generally more likely to translate into more effective therapies, possessing a greater overall safety profile and requiring lower therapeutic doses. However, with regard to the first assumption, from this study and many others in the literature, it seems that the safety profile (ADMET and off-target related effects) is more likely to be inversely correlated with the level of target potency given their opposing relationship with regard to key physicochemical properties*” [9]. The same authors showed that *in vitro* potency can only explain roughly 30% of the variation in dose. Having the right screening cascade to balance out the various properties is critical and prevents late stage surprises. A somewhat generic example for a CNS target is presented in Fig. 3.3.

Table 3.6 summarizes the key physicochemical parameters—both molecular and specific structural features—that influence various ADME properties listed in the third column. Note that many physicochemical parameters are not independent of each other. For example, if the MW increases, the number of rotatable bonds usually increases as well, and the PSA and the total number of HBDs and HBAs are also correlated. The interconnectivity between the physicochemical parameters and the ADME properties have been illustrated with several literature and in-house examples.

The first PK hurdle that oral drugs encounter is absorption. Absorption is influenced by both solubility and permeability. In general, solubility increases with increasing HBD and HBA count, PSA, and the fraction of the bonds that can freely rotate, but is negatively influenced by increasing $\log P$, $\log D$, and the number of aromatic rings [63,70]. However, the exact opposite is usually true for permeability and this necessitate identification of a physicochemical “sweet spot” for absorption. The situation is even more complex if absorption is limited by intestinal efflux. A nice example illustrating the level of complexity was presented by Lévesque *et al.* [71]. The authors were trying to identify a rennin inhibitor for blood pressure control. Earlier, lipophilic compounds with a basic amine functionality were potent and orally bioavailable but suffered from CYP 3A4 and hERG inhibition. To address the latter liabilities, while maintaining potency, the size and lipophilicity of the leads were reduced significantly, but this resulted in negligible bioavailability. Increasing the dose improved the bioavailability somewhat, but the clearance did not change. This, combined with the observation that the majority of the drug was detected in the feces after oral dosing in bile duct cannulated rats, suggested P-gp limited absorption. Indeed, P-gp KO (knockout) mice and rats codosed with elacridar (a P-gp inhibitor) showed improved bioavailability (but no change in clearance). All these compounds showed very poor permeability in LLC-PK cells and, therefore, it was impossible to determine the efflux ratio in LLC-PK cells overexpressing P-gp. Thus, the authors prepared more lipophilic compounds ($\log D_{7.4} > 1.7$) and this increased the passive permeability significantly ($P_{app} > 10 \times 10^{-6}$ cm/s). The latter did not eliminate the efflux as detected in the P-gp overexpressing

TABLE 3.6 Molecular and Structural Features that Influence ADME Properties

Molecular Features	Structural Features	ADME Properties
Molecular weight	Hydrogen bond donors	Solubility and dissolution rate
Molecular volume	Hydrogen bond acceptors	Permeability
pK_a	(Aromatic) rings	Absorption
$\log P$	% sp^3 carbon atoms	Plasma protein binding and tissue binding
$\log D_{7.4}$	Rotatable bonds	Red blood cell partitioning
Polar surface area		Clearance (metabolic, transporter-mediated, passive renal, or biliary)
% Polar surface area		Distribution (including transporter-mediated uptake or efflux)
		Inhibition and induction of drug-metabolizing enzymes and transporters

Figure 3.9 Relationship between $\text{clog } D_{7.4}$ and the measured A to B permeability in MDCK cells for a large number of compounds synthesized for an in-house project.

LLC-PK cells (efflux ratio ≈ 20), but the *in vivo* impact was drastically reduced and the bioavailability of many of the more lipophilic compounds exceeded 25%. However, not all the more lipophilic compounds showed good bioavailability and this was ascribed to a significant first-pass effect. Thus, the lipophilicity was modulated to balance potency, bioavailability, CYP inhibition, and hERG. The same phenomena are illustrated in Fig. 3.9 based on data from an in-house project. The AB permeability in MDCK cells is plotted as a function of the $\text{clog } D_{7.4}$ and illustrates that a $\text{clog } D_{7.4}$ of at least 2 is needed to achieve acceptable permeability, although it does not guarantee it. Data not presented here indicated that a $\text{clog } D_{7.4} > 3$ increased the probability of poor solubility and high clearance, resulting in a narrow “sweet spot.”

There appears to be a Gaussian or parabolic relationship between the $\log D_{7.4}$ and the extent of absorption and bioavailability [72]. At $\log D_{7.4} < 0$, a compound's solubility is usually good, but its permeability across membranes is poor resulting in limited absorption. In contrast, at $\log D_{7.4} > 5$, the membrane permeability is adequate, but the solubility is low, which significantly reduces absorption. In addition, metabolic clearance in the intestine and liver, which affects F_g and F_h , tends to be higher for compounds with $\log D_{7.4} > 5$. However, this effect appears to be modulated by MW with the $\log D$ range that leads to good absorption and metabolic stability being wider at low MW than at high MW [73]. The PSA is another important parameter for passive membrane permeability with a PSA in excess of $120 \text{ \AA}^2$ associated with poor absorption

[74] and in excess of $90 \text{ \AA}^2$ associated with poor brain penetration [17]. This effect can be ascribed to decreased membrane permeability for polar compounds. In contrast, a very low PSA ($<50 \text{ \AA}^2$) can lead to increased intestinal and hepatic extraction [72].

Two common approaches to identify absorption issues are the maximum absorbable dose (MAD) and the dose number (D_0).

$$\text{MAD} = k_a \cdot S \cdot V_{\text{intestine}} \cdot T \quad (3.2)$$

where k_a is the absorption rate constant (usually obtained from PK studies in preclinical species); S the solubility of the drug in a relevant medium; $V_{\text{intestine}}$ the volume of water in the small intestine available to dissolve the drug (usually 250 mL in humans); and T the small intestine transit time (usually 4 h for the small intestine in humans).

$$D_0 = \frac{D}{(V_{\text{intestine}} \cdot S)} \quad (3.3)$$

where D is the dose, $V_{\text{intestine}}$ the volume of water in the small intestine available to dissolve the drug (usually 250 mL in humans), and S the solubility of the drug in a relevant medium.

The parameters influencing the MAD and D_0 are fraught with experimental uncertainty, most of all the solubility. The solubility determined in discovery is usually kinetic in nature and the true thermodynamic solubility is not available until later. Moreover, the solubility is strongly influenced by the solvent system (buffered solvents or fed or fasted state simulated intestinal fluid) and its pH and the physical form of the drug (amorphous or crystalline, the most stable polymorph or not, presence of excipients, etc.). In addition to the extent of solubility, the dissolution rate should be taken into consideration as well and both the MAD and D_0 ignore this aspect. Nevertheless, the MAD is easy to calculate and provides a crude guide; if the MAD is $<10\%$ of the anticipated human dose, one should consider the possibility of dose-limited absorption. Similarly, if the dose number is >10 , absorption could be incomplete. Note that these numbers are merely indicators of absorption risk and should be used as impetus to explore absorption further.

Once absorbed, the clearance is usually the most important parameter. An analysis of the routes of elimination of the 200 most prescribed drugs indicated that for about 72% of the drugs, metabolism was the major route of drug elimination, whereas renal elimination and biliary clearance were prevalent for 25% and 3%, respectively, of the top 200 drugs [75]. For those drugs predominantly cleared via metabolism, the CYP enzymes were the major contributors to metabolism. Considering the trend toward higher MW compounds (as illustrated in Table 3.2), it is reasonable to assume that passive renal clearance will be low for most drugs and that the major component of clearance will be either metabolism or active excretion into the bile, urine, or intestine. It is well established that increasing the lipophilicity can lead to increased clearance. In addition, increasing the PSA and the HBDs and HBAs decreases the clearance [72]. However, it is imperative to focus on the unbound or free clearance. The unbound clearance can be obtained as follows:

$$\text{CL}_u = \frac{\text{CL}}{f_u} \quad (3.4)$$

where CL is the total clearance, CL_u the unbound or free clearance, and f_u the unbound fraction in plasma.

In keeping with the concept that in most cases, efficacy is driven by the amount of unbound drug available, it is imperative to convert the relevant PK parameters to their unbound equivalent (e.g., AUC_u and CL_u). Too often, drug discovery efforts lead to an increase in lipophilicity and, consequently, a smaller f_u , while maintaining or sometimes even improving CL. This could result in a false sense of success. Instead, teams should focus on the CL_u value (which reflects the free amount of drug to drive efficacy), which may have increased dramatically. It is also important not to optimize f_u or use it to prioritize compounds for further studies. There is no optimum f_u and, indeed, there are many successful drugs with small free fractions [38]. Interestingly, there is a difference between the effect of plasma protein binding *in vitro* and *in vivo* [39]. *In vitro* an increase in f_u from 0.1 to 0.5 by changing the structure of the compound increases the unbound concentration five-fold as the total concentration remains the same. *In vivo* after an oral dose, an increase in f_u from 0.1 to 0.5 will increase the unbound concentration only if the intrinsic hepatic clearance decreases at the same time. If the intrinsic hepatic clearance stays the same, an increase in f_u from 0.1 to 0.5 will not increase the unbound concentration and will reduce the total concentration. Thus, the goal should be to optimize the physicochemical parameters such that it leads to a lower intrinsic clearance. Obach *et al.* [76] performed a detailed analysis of 670 drugs administered to human intravenously, which allowed determination of the clearance and volume of distribution. Their analysis showed that the unbound clearance increases dramatically with the lipophilicity with hydrophilic compounds with a $\log P$ between 0 and 1 having a median unbound clearance of 8.5 mL/min/kg and very lipophilic compounds with a $\log P > 4$ having a median unbound clearance of 150 mL/min/kg. The relationship between $\text{clog } P$ and the free fraction for three chemical series in one project is illustrated in Fig. 3.10 and shows that the free fraction steadily decreases with increasing lipophilicity, although the three chemical series are offset from each other. Another in-house analysis involving more than 2200 compounds across all projects came to the same conclusion. Specifically, 54% of the compounds with a measured $\log D_{7.4} > 4$ have a free fraction smaller than 0.01, whereas only 6% of the compounds with a measured $\log D_{7.4}$ between 1 and 2 have a free fraction smaller than 0.01. Conversely, 66% of the compounds with a measured $\log D_{7.4}$ between 1 and 2 have a free fraction >0.1 , whereas only 3% of the compounds with a measured $\log D_{7.4} > 4$ have a free fraction >0.1 . A graph derived from the data compiled by Obach *et al.* [76] is presented in Fig. 3.11 and displays the correlation between f_u and CL_u . The implication of this graph is that lowering the lipophilicity may actually have a dual effect by lowering CL_u and increasing the free fraction. Of course, lowering the lipophilicity may reduce the potency (because of less interaction with the target) and decrease the permeability. An analysis (Fig. 3.12) based on rat PK data for more than 50 compounds in one project shows how sensitive the relationship can be. If the $\text{clog } P$ value is <1 , more than 90% of the compounds have an unbound clearance of <170 mL/min/kg, whereas with a $\text{clog } P$ value >2 , only 32% of the compounds have an unbound clearance of <170 mL/min/kg.

A nice example of optimization of physicochemical parameters is illustrated by the discovery of crizotinib. Initially, crizotinib was positioned as a c-MET inhibitor. Later it was also found to inhibit anaplastic lymphoma kinase (ALK) and it was launched as treatment for non-small-cell lung cancer in 2011. The original lead candidate, PHA-665752 (Fig. 3.13), demonstrated poor PK and pharmaceutical properties,

Figure 3.10 Relationship between $\text{clog } P$ and the measured free fraction (f_u) in plasma for a large number of compounds synthesized for an in-house project.

Figure 3.11 Relationship between the measured free fraction (f_u) in plasma and the unbound intrinsic clearance ($\text{CL}_{u,\text{in}}$) derived from data presented in Ref. 76.

Figure 3.12 Relationship between $\text{clog } P$ and unbound clearance (CL_u) in rats for more than 50 compounds synthesized for an in-house project.

Figure 3.13 Optimization of the original lead c-MET inhibitor, PHA-665752, leading to the dual c-MET/ALK inhibitor, crizotinib.

which limited its development as a clinical candidate despite good cell potency (c-MET cell IC_{50} = 9 nM) and selectivity [77]. For example, the clearance of PHA-665752 in rats was higher than hepatic blood flow, 77 mL/min/kg [78], and it had low permeability and poor solubility at pH 7.4, 0.9 μ g/mL, which prevented nomination as a potential intravenous treatment [77]. PHA-665752 having a high MW, 641.6 Da, and being quite lipophilic (log $D_{7.4}$ = 3.2 and LipE = $pIC_{50} - \log D_{7.4}$ = 4.8), the goal was to identify equally potent compounds with improved physicochemical properties. Detailed SAR studies, fueled to a large extent by cocrystal structures of compound bound to c-MET, led to PF02341066, crizotinib. Crizotinib still makes the same key interaction with the c-MET protein, but is much smaller with a MW of 450.3 Da. Considering the lower lipophilicity, clog $D_{7.4}$ = 2.0, and a similar cellular potency in the c-MET assay, 8 nM, the LipE of crizotinib is improved to 6.1 [77]. Moreover, the solubility is improved and the same applies to the preclinical PK (e.g., the clearance values in rat and dog are 29 and 9 mL/min/kg, respectively, and the bioavailability values are 63% and 65%, respectively). The human dose is 250 mg twice daily (BID), the half-life is 43–51 h, and there is no food effect, which defines an attractive clinical profile [79].

An interesting computational approach to improve clearance was proposed by Keefer *et al.* [80]. They performed a very comprehensive pairwise analysis of a large database of compounds with metabolic stability data in human liver microsomes, permeability data in RRCK cells (MDCK cells with lower levels of endogenous transporters), and P-gp-mediated efflux in MDCK cells overexpressing P-gp. They determined the 20 most frequently occurring transformations in their database and their mean change and standard deviation associated with the three *in vitro* ADME parameters described above. A few examples and their impact on microsomal metabolic stability and RRCK permeability are presented in Table 3.7. They also showed that transformations that involve multiple steps are frequently additive. However, their analysis also showed that similar transformations in very different molecules may not always have the same net effect and sometimes they even have the opposite effect. Nevertheless, it provides a

TABLE 3.7 Statistical Changes in Metabolic Stability in Human Liver Microsomes and RRCK Permeability Associated with the Most Common Transformations Based on a Pairwise Analysis of a Very Large Database

Transformation	HLM Stability		RRCK Permeability	
	Mean Change	%Increase/% Same/% Decrease	Mean Change	%Increase/% Same/% Decrease
$R_1-H \longrightarrow R_1-CH_3$	21.9	45/41/12	-0.2	24/47/28
$R_1-H \longrightarrow R_1-F$	2.7	24/56/18	-0.5	17/55/26

simple (computational) rule of thumb to increase the likelihood to identify compounds with improved ADME properties.

Finally, it is important to recognize that multiple enzymes can contribute to the metabolism of compounds and, if the choice of *in vitro* studies and preclinical PK studies is not comprehensive enough, the data can be deceiving. A classical example is carbazeran (Fig. 3.14). Carbazeran is relatively stable in microsomes across species and the PK in dogs looks good with a CL of 11.5 mL/min/kg and a bioavailability of 68% [81]. In sharp contrast, the clearance in humans was 38 mL/min/kg, which is higher than hepatic blood flow, and carbazeran was not detected in the plasma after an oral dose of 350 mg. Subsequently, it was determined that human metabolism was mainly via aldehyde oxidase leading to oxidation of the phthalazine moiety. Moreover, dogs have very low levels of aldehyde oxidase, which explains the good PK in dogs. Had the investigators used either hepatocytes, S9 or cytosol, to examine the metabolic stability of carbazeran across species before nominating the compound for development, they would have identified the aldehyde oxidase liability in humans. Remarkably, compounds failed in the clinic as recent as 2011 due to extensive aldehyde oxidase metabolism in humans (e.g., FK3453 [82] and BIBX1382 [83]; see Fig. 3.14 for structures) despite the ability to identify the liability preclinically by doing the right *in vitro* studies or performing a monkey PK study.

Another important parameter to consider is the volume of distribution and, not surprisingly, Obach *et al.* [76] have shown that the volume of distribution, and in particular the unbound volume of distribution, increases with the lipophilicity. In addition, the volume of distribution decreases with the PSA and the number of HBDS and HBAs. The combined data for clearance and volume of distribution are summarized in Table 3.8 by charge state. Note that the V_d and CL are generally much lower for acids

Figure 3.14 Structures of the aldehyde oxidase (AO) substrates carbazaran, FK3453, and BIBX1382. The sites of AO metabolism are indicated by arrows.

TABLE 3.8 Comparison of Median Values for Total and Unbound V_d and CL Values Relative to Charge Type

	Median V_d	Median $V_{d,u}$	Median CL	Median CL_u
Acids ($n = 159$)	0.22	2.2	2.1	17
Neutrals ($n = 173$)	1.1	5.5	4.0	21
Bases ($n = 267$)	2.3	9.2	7.6	23
Zwitterions ($n = 68$)	0.83	2.0	2.4	3.8

Source: Data from Obach *et al.* [76].

than bases, but the differences are reduced after correcting for plasma protein binding. If the drug target is in the brain, particular attention should be paid to CNS distribution. As described above, a TPSA in excess of $90 \text{ \AA}^2$ is associated with poor brain penetration [17]. This is partly due to poor passive permeability, and it also appears that the probability for P-gp-mediated efflux increases with a TPSA above $70\text{--}80 \text{ \AA}^2$, as illustrated in Fig. 3.15 for data from multiple chemical series for one particular in-house CNS target.

Obviously, there are numerous other parameters that play a role in drug design and ADME is only one of them. For example, the desire to increase potency frequently results in larger and more lipophilic compounds. This necessitates finding a “sweet spot” that represents the best overall balance. A generalization of the dependence of various ADME parameters on the key physiochemical properties is summarized in Table 3.9.

Figure 3.15 Relationship between TPSA and the A to B permeability in MDCK cells (A) and the B to A/A to B efflux ratio in MDCK cells overexpressing MDR1 for a large number of compounds synthesized for an in-house project. (a) Permeability versus TPSA and (b) MDR1 efflux ratio versus TPSA.

TABLE 3.9 Generalization of the Dependence of Various ADME Parameters on Physicochemical Properties

	$\log D$	MW	PSA	HBA + HBD
Solubility	↓	↓	↑	↑
Permeability	↑	↓	↓	↓
F_a	↑	↓	↓	↓
F_h	↓	=	↑	↑
CL	↑	—	↓	↓
F	Gaussian (↑ then ↓)	↓	Gaussian (↑ then ↓)	↓
V_d	↑	—	↓	↓
Plasma protein binding	↑	—	—	↓

^aThe arrows indicate an increase, no change, or decrease in the pharmacokinetic parameter in one of the rows as a function of an increase in the physicochemical parameter in one of the columns.

Finally, ADME scientists play a critical role in other aspects of drug discovery such as identification of drug–drug interaction liabilities, determination of exposure in PD and efficacy studies, PKPD analysis of preclinical data, and human PK and dose predictions. Detailed descriptions of these aspects are beyond the scope of this chapter and the readers are referred to others chapters in the Encyclopedia of Drug Metabolism for these components.

3.11 CONCLUSIONS

It is realistic to state that incorporation of ADME parameters early on drug discovery has had and will continue to have a positive impact on drug development. However, drug candidates have become larger and more lipophilic to meet potency criteria and this has in general a negative impact on ADME parameters and drug development in general. Before engaging in an extensive drug discovery effort, it is important to clearly define the acceptable target candidate profile and identify any attenuating circumstances that could influence the profile. Next, a thorough effort to establish the SAR of all key parameters (potency, selectivity, permeability, clearance, etc.) should be conducted, and finally, the physicochemical “sweet spot” that provides the best balance of properties should be identified.

4.1 INTRODUCTION

The process by which a new chemical entity (NCE) results in a new medical entity (NME) that, when administered to patients, results in a successful therapeutic intervention that improves the patients' quality of life is a long and costly process. This has remained so in spite of advances in all of the sciences that are contributors to and constitute the process. Even with the result of a greatly increased number of NMEs with promising pharmacological properties being routinely identified, the challenge remains: which molecule will be predictive of efficacy and safety in humans and what is the process that will support these outcomes?

In drug development, each pharmaceutical company has its own system, which (probably) is a reflection of previous successes. Although when "all is said and done," drug candidates become drugs by going through similar stepwise regulatory-driven process that demonstrates safety and efficacy. In this context, a faster and less costly process as a definition of "efficient drug development" is highly unlikely. This does not preclude that within the process, the attainment of conclusive Go/No-Go milestones can be attained effectively (efficiently) and thus result in an efficient process overall. In

this context, the addition of effective drug development should also be used in defining drug development.

Considering the number and diversity of molecules for potential development, some with multiple activities with active indication profiles, an all encompassing treatment of drug development is beyond the scope of this chapter. Thus, we have not attempted to be all inclusive or exhaustive in terms of a drug class or indication or to compile a drug development study checklist with the intent of “one size fits all.” Instead, we have attempted to present in outline concepts that define aspects/landmarks of early nonclinical and clinical development, as these concepts contribute to the traditional path to facilitate the first developmental outcome desired: an open investigative new drug (IND).

In one respect, drug development can be considered as a single path with a single outcome. However, it is not a line-driven process. Once started, the path forward quickly branches into the primary disciplines that will support safety and efficacy, which in turn develop subbranches to form a mosaic(s) to constitute total development as defined in the new drug application (NDA). Every path has to have a beginning: the path forward for a formal drug development is the IND. It should be stated that the IND, once opened, precedes the conduct of the multidisciplinary studies that continue mostly by paths that validate drug safety and efficacy. Once the initial studies are supportive of further development, continuation of full panels of studies are conducted on the way to the NDA. All of the studies that will define the content of the NDA are not addressed here in detail; however, for continuity of the development process, descriptions of IND-targeted studies that are germane to further development are presented. This theme will be defined and expanded further in some detail and is introduced here.

In early drug development, nonclinical studies are conducted in two to three species to determine a dose–toxicological profile in relationship to the proposed human dose (animal to human safety margins) in the first clinical trial(s), that is, phase 1.

It is important to state that phase 1 (and phase 2a) studies are the *learning phases* of drug development and, if appropriately coordinated and conducted, provide information that increases the efficiency/effectiveness for the rest of the drug development process [1]. In addition, phase 1 provides decision-making data and information for labeling. Some examples of such coordination and impacts on decisions will be presented later. In this context, the pivotal phase 3 studies (and phase 2) of drug development are *confirmatory studies* that define the safe and effective use of the drug in the targeted patient population. Careful consideration for the selection, design, and timing of phase 1 trials provide a solid foundation for the conduct of one or two proof of safety and efficacy studies in phase 3. The final approval process as entailed in phase 3 is outside the scope of the present report.

In addition, recent use of techniques such as biomarkers and surrogate markers [2–4], pharmacokinetic/pharmacodynamic (PK/PD) correlations [5], and microdosing [6], all of which can increase the understanding of the drug PK/PD properties in both early and later stages of development, are outside of the scope of this present report. These are mentioned as they are utilized in current drug development. The use of biomarkers and surrogate markers to define/predict clinical outcomes is an important consideration to an efficient drug development process [7]. As biomarkers and surrogate markers are developed, it must be kept in mind that the time to think about their selection should be early in the drug discovery and development process. Thus, a linkage(s) to clinical outcomes will transition the marker into a surrogate end point

and have a prospective value as the surrogate will predict an outcome. An essential component in the selection of biomarkers and surrogate markers is their validation. In this context, information must not be confused with knowledge and reliability with validity. The criteria for validity should be concurrent in that supporting evidence is obtained at the same time, predictive in that the evidence is also obtained at a later time, and prescriptive by providing the appropriate treatment.

More recently, the use of genotyping/phenotyping to provide information for predicting drug response and variation that are currently used with increasing regularity are also mentioned only in passing. These ultimately do contribute to the overall aspects of development, especially as polytherapy is the norm in today's aging population to provide effective patient management and contain the promise of individual therapy [8–12], but at present, this remains in the future.

To provide an adequate bibliography is prohibitive; thus, an abbreviated list of reference citations is provided for additional and in more depth insights for the process of drug development. Considering that drug development is essentially a regulatory process, FDA guidance documents are also included where applicable to provide a regulatory framework for the concepts presented.

4.2 OVERVIEW OF DRUG DEVELOPMENT

The basis for the marketing approval of a NME is safety and efficacy. To this end, the *road map* to develop a drug is both defined and regulated by FDA and ICH (International Committee for Harmonization) guidances. However, a road map primarily gives us the destination. To efficiently navigate, the road map requires both a plan and *road markers* that can ascertain progress as one moves forward. These road markers are studies and, even more importantly, data that are *needed* (not what can be generated) for Go/No-Go decisions. Even with these guides, there are few specifics provided that are “Not to Do”. However, the specifics of what to do, how to do it, and how to evaluate the validity of the results obtained during the drug development process remains time consuming and costly. This is true in spite of the very large number (e.g., 100,000) of new molecules that are synthesized yearly, the availability of high throughput screening for determining pharmacological activity, validated *in vitro* and *in vivo* disease models, the use of genomics and proteonomics, and other new and innovative technologies to expedite drug discovery and development. The expectation for new and numerous drugs available for therapeutic use have not been met, and in fact, there is a decline in the new drug discovery/development pipeline.

When all is said and done, only 1–2 of the 100,000 molecules actually reach the market for therapeutic use after a development time of 7–12 years (or more) and costs that can exceed \$700 million before an NDA is submitted to the FDA and filed for their review and evaluation. The review of the NDA adds additional time of 10–18 months until marketing approval. A goal during development is to obtain Go/No-Go milestones as quickly as possible to maintain the entry of drug dossiers for review by the regulatory agency. An outline of the development process (road map) is shown in Fig. 4.1 in which drug development is outlined in distinct phases. In addition, guidance documents issued by the FDA are available, which address specific studies/aspects of development, provide a wealth of specific information [13], and provide efficiency to a development process by resulting in an effective drug development.

Figure 4.1 New drug development process.

Figure 4.1 outlines the distinct phases of drug development: discovery, preclinical studies (pharmacology and toxicology/safety, which lead to an open IND, enabling the first study(ies) in humans), the phase 1 studies (clinical pharmacology), followed by the phases 2 and 3 clinical studies that demonstrate and confirm safety and efficacy and thus provide the basis for marketing approval.

Discovery/screening studies are not included herein, as these are drug/indication specific and as such beyond the scope of the present report. Needless to say, those type of studies are carried out in order to provide a rationale for the development of the lead candidate(s). Usually, a relatively small number of such studies are conducted; the positive results from which support a rationale for further development. It is not uncommon that four to five animal pharmacology studies suffice, two or three of which hit the desired end point. Such an approach is alluded to in the *Exploratory IND Studies* guidance document [14] issued by the FDA as one of the steps to facilitate the entry into the ultimate model: humans. The phase 2 and pivotal phase 3 studies are also not addressed; the emphasis is on the traditional segment of drug development that is representative of what constitutes learning to understand the drug and thus allows development to move forward into the confirmatory aspects of drug development (phase 2b and phase 3) on which marketing approval is ultimately based.

The concepts that will be described are for the development of an oral drug, as this is the most desired commercially, and perhaps the most prevalent, route of administration from several perspectives. However, the development of a drug with vascular (or topical) administration would follow the same path (type of studies) to establish the safety profile of the intended route of administration for the management of patients.

4.3 REGULATORY CONSIDERATIONS

Drug development is subject to numerous the FDA and ICH guidances and regulations [Good Laboratory Practices (GLPs), Good Clinical Practices (GCPs), etc.]. These provide a wealth of information on both specific and general issues that contribute to any drug development process.

The need for more *better and cheaper* drugs is a widely used phrase. At a relatively recent national meeting, the FDA shared their concerns to this end by presenting data showing that new compounds entering phase 1 today have an 8% chance of reaching the market (vs. 14% chance 15 years ago); the failure rate in phase 3 is 50% (vs. 20% 10 years ago). In this context, the FDA is actively pursuing a critical path initiative (CPI) [15] in the attempt of modernizing the techniques and methods used to evaluate safety, efficacy, and quality of drugs as they move through the development and approval processes. The three areas of the CPI are (i) a new approach to clinical trials in terms of early proof of concept (POC) studies, computer modeling, microdose studies, and new and innovative methods of data analysis; (ii) the FDA will issue a guidance on the validation of biomarkers and surrogate markers; and (iii) the use of modeling and simulations. It is hoped that these will expedite the entry of drugs into the marketplace.

4.4 IND-ENABLING DEVELOPMENT

Drug development has its beginnings in pre-IND as the following factors are considered:

- understanding the disease process and therapeutic approach;
- determining the mechanism of action and establishing appropriate models;
- identifying and validating clinical safety and, if possible, efficacy markers for decision making;
- conducting *in vitro* metabolism screens using toxicology species and human liver microsomes to identify the cytochrome P450 (CYP450) isozymes involved;
- developing the appropriate toxicology–safety program (see ICH guidance).

At some time during the above development, it is advantageous to write a draft label for the indication sought, as this will provide focus to all aspects of drug development as it moves forward. It is also important to address the manufacturing of the drug substance and set the impurity limits/specifications and prepare the clinical supplies for the first human studies. At this stage, it is not necessary to have a final galenic formulation for the initial clinical studies, as these first such studies can easily be conducted with simple hand-packed capsules. It is given that the galenic formulation is ongoing for formal drug development. Also, in parallel, the impurity profile—qualitative and quantitative—is determined. This is important to ascertain that the drug substance used in the animal toxicity/safety studies that were conducted to open the IND did not have an impurity profile that exceeds that of the drug substance that is to be used in the initial clinical trials.

Using the FDA-recommended Exploratory IND, as mentioned previously, is an efficient and effective roadmap to an acceptable IND, in that a Go/No-Go decision can be reached relatively quickly and may include a pivotal first study in the ultimate model: humans. It is worth repeating that 15% of drug development programs fail at phase 1. In general, the Exploratory IND consists of a panel of general *in vitro* and *in vivo* safety pharmacology, toxicology/safety studies in two animal species, with the duration of such studies linked to the duration of the proposed post-IND trial. Safety pharmacology/toxicology (cardiac safety including a QTc prolongation in the telemetry dog), genotoxicity, and ADME (absorption, distribution, metabolism, and excretion) studies are normally required for the Exploratory IND before dosing in humans.

In this context, the current regulatory environment encourages INDs with minimum content, that is, pharmacology to support a rationale for drug development and appropriate animal toxicity–safety studies that allow development to move forward into the first studies in humans (exploratory INDs). Thus minimum as describing the requirement for the IND are a misnomer; the studies provide key nonclinical information for conduct of a human PK study. However, there are no shortcuts, and if development is to move forward, additional toxicology studies will be conducted at higher doses and with increased duration.

There is always value in stating (or restating) what has been (and will remain) the foundation of drug development: the IND. The IND consists of the following sections:

- Form FDA 1571
- Table of contents

- Introductory statement
 - List of references
- General investigational plan
 - Clinical development plan
 - Planned exposure
- Investigator's brochure (IB)
- Protocols
- Chemistry, manufacturing, and controls (CMC)
- Nonclinical pharmacology and toxicology
- Previous human experience
- Additional information.

It is important to have a clear objective(s) for the first human studies (phase 1) as this will have a direct impact on the nonclinical pharmacology and toxicology studies that will precede it. In this context, it is of value to utilize the FDA guidance document titled Exploratory IND Studies, which provides concepts that facilitate an early entry into clinical studies by focusing on the core nonclinical studies required. It should be stated, however, that should development move beyond the first phase 1 study and into formal development, it will be necessary to go back and conduct the studies that constitute a traditional IND/NDA.

4.5 ANIMALS TO HUMANS

Once a candidate for development has been chosen, the first goal is to obtain an open IND, thus allowing the first study in humans. As was outlined above, the dossier for the IND is started by conducting a series of nonclinical toxicology/safety studies that includes at least two animal species, usually rat and dog, that emerge as the primary species for the determination of a toxicologic and safety profile projected for human exposure.

Throughout the whole process (IND to NDA), measuring drug concentrations to determine the extent and duration of systemic exposure to the drug provides windows of understanding of both safety and efficacy (or the lack thereof). This is true of non-clinical toxicity/safety [toxicokinetics (TK)] and clinical studies (PK). The fundamental difference in animal studies and human studies can be outlined as follows:

Animals	Humans
Once/day dosing; defined regimen	qd, bid, tid, qid; widely varying regimens
Wide range of doses/dose strengths	Single, two to three strengths with narrow range
CMC suspensions, dietary admix (rats); neat drug in capsules (dog)	Elegant galenic formulation
Species differences	Ethnic and gender and/or age differences

4.5.1 Bioanalytical Considerations

As was stated above, the systemic exposure to the administered drug and the elucidation of its dispositional parameters is of importance. To this end, it is mandatory to develop and validate the analytical methods that would support both nonclinical and clinical studies. Usually, the method utilized for determining different aspects of the drug substance, for example, dose verification, purity, and stability is high performance liquid chromatography (HPLC). For determining drug concentrations in animal and human biofluids (blood, plasma, urine, tissues), the usual method(s) is LC/MS-MS (liquid chromatography/mass spectrometry/mass spectrometry) assay(s) for its sensitivity [low limit of quantitation (LOQ)] and specificity for drug (and metabolite). Validated bioanalytical methods for animal studies (TK, ADME) and humans studies characterize the biopharmaceutics (BP) and PK for phase 1/phase 2a clinical pharmacology studies. Thus, such bioanalytical methods are conducted under GLP regulations. The validation of such assays results in stand-alone reports that demonstrate selectivity, accuracy, precision, reproducibility, and recovery [16]. As most biological samples (animal/human) are stored frozen and bundled prior to assay, short- and long-term stabilities are required. The inclusion of BP and PK principles in the conduct and evaluations of animal toxicity/safety studies and GLP toxicity studies is virtually mandated. Using full or sparse sampling profiles over selected time points over the course of toxicology studies, TK provide drug systemic drug concentration data that aids in understanding the findings.

As development moves forward, a validated LC/MS-MS assay for drug and primary metabolite in human plasma (and urine) with a low LOQ should also be developed, the report(s) of which should be included in the IND in support of the conduct of the first phase 1 PK study.

4.5.2 Early Nonclinical Pharmacology and Toxicology

An IND-targeted program will start with nonclinical pharmacology and toxicology to provide the data from which safety assessment can be projected for safe use in the first human studies. The early nonclinical toxicology program to support an open IND is outlined below, although details of study design are not addressed. It should be stated that the success/failure of drug development program can depend on the early nonclinical toxicology/safety studies that provide a rationale/guidance for effective evaluation that provides rational safety margins [17]. Only selected studies are addressed, and specific guidance documents are referenced for additional information. As development continues, the nonclinical toxicology dossier ends up being one of the major portions of the NDA; a full in-depth review is not feasible within this report. However, in the guidance for the format and outline of the toxicology section of the NDA, one can obtain specific design information from the table of contents [18].

Acute toxicity studies [19] are the initial nonclinical studies conducted. These are usually conducted in rats, although a second species may be used. There are two basic study designs: escalating doses in the same animal with a 14-day observation period with incremental doses to ascertain any latent toxicity or escalating doses in parallel groups with a 14-day observation period. Doses are escalated until a clear toxicological outcome is reached. There is no requirement for conducting acute studies under the GLP regulations. However, most Sponsors do conduct these studies under GLP, in that

if a global marketing strategy is contemplated and proceeds forward, some overseas regulatory agencies require that acute toxicity be conducted under GLP regulations. As was stated above, acute toxicity studies are dose escalation studies, the primary objective is not to cause mortality per se but to have a clear concept of the dose–toxicity relationship (food consumption, body weight loss, clinical pathology findings, etc.) as an acute response and/or a delayed response after dose administration. In addition, the acute toxicity response may provide a window for investigating potential human overdose. It should also be mentioned that gross pathology, histopathology, or clinical pathology are not requirements; however, body weight loss, gross pathology, and the addition of key clinical chemistry indicators can be used in establishing a dose at which toxicity begins.

To ascertain, no potential for genotoxicity is a benchmark in early development. The core genotoxicity studies are the Ames test with and without S9 activation, chromosomal aberration (CHO), and *in vitro* mouse micronucleus test [20,21]. If there are no findings indicative of genotoxicity or mutagenicity, no further genotoxicity testing is required. If the genotoxicity results are positive in identifying a signal for mutagenicity, the relationship to dose relative to the first human dose should be carefully examined. It is possible that the program should be stopped as the genotoxic dose is too close to the proposed human dose.

The safety pharmacology studies in Refs 22,23 represent the *in vitro* and *in vivo* panel of nonclinical studies that support cardiac safety during an open IND. These are acute administrations at doses that result in systemic concentrations that are at least 100× the human plasma concentration of the projected clinical dose. These studies are conducted in animal models to identify undesirable PD properties of the NCE that may have a relevance to human safety. The core battery of safety pharmacology trials [22] addresses organs or systems toxicities and includes the following.

1. Effects on the central nervous system are assessed in terms of motor activity, behavior changes, coordination and sensory/motor reflex responses, and learning and memory.
2. Cardiovascular system studies assess cardiac output, ventricular contractility, blood pressure, heart rate, and the ECG (electrocardiography) *in vivo* (telemetry dog) and *in vitro* repolarization and conductance [23]. The effects of *in vitro* hERG potassium channels expressed in human embryonic kidney cells on cardiac ionic currents are assessed. Also, isolated rabbit Purkinje fibers assess the effects on a potential changes in the action potential duration (ADP). These *in vitro* studies are routinely conducted to be complementary to the human study.
3. Respiratory system assessed by measurements of the respiratory rate and function.

The duration of the proposed clinical studies are directly linked to the duration of the animal toxicity studies: two-week studies in two animal species (usually rat and dog) allow two-week studies in humans. It is usually more efficient to conduct four-week toxicity studies at this time, which will allow more flexibility for the first human study(ies). As early nonclinical trials indicate a signal in regard to the relationship to safety and an advantageous PK profile of the drug candidate, animal studies of longer duration (e.g., 4 and 13 weeks in rats and dogs, 6 month in rat, 9 month in dogs, 2-year carcinogenicity in mice and rats, the full panel of reproductive toxicity in rodents) will be conducted in sequence. These tabulated studies are needed to obtain an open IND

and thus allow the conduct of the first human studies (PK/tolerance) to initiate formal drug development [14,18].

In this context, the challenge in the early development program is to set the doses for the first animal toxicity study. It is not recommended to guess at the dose level because of either underdose or overdose and therefore, not allowing one to obtain an accurate picture of the dose–toxicity relationship. The early conduct of the acute toxicity studies (rats and dogs) can provide some information for setting the doses for the two-week toxicity studies, although conducting a 7-day dose range finding study with initial and terminal TK is more informative. The inclusion of TK into the acute toxicity studies is not a requirement; however, TK can focus on the drug plasma concentration relationship and the onset of toxicity.

Today, the inclusion of TK in toxicology studies is assumed [24]. In addition to ascertaining systemic absorption and a level of exposure of the drug in animals, it is also important to understand the systemic disposition of the drug in animals relative to human studies. Thus, the conduct of animal ADME studies is important in this transition. Animal studies with IV and oral dosing can be readily conducted to obtain a metric of bioavailability (BA), area under the curve (AUC), half-life, clearance, and volume of distribution. All of these parameters provide an understanding to the TK determinations that are routinely obtained from the toxicology studies performed.

It is prudent in early development to conduct studies that determine the metabolic profile of the drug using standard protocols and that utilize rat, dog, and human hepatocytes and microsomes (i.e., the metabolic stability of the drug). Drug metabolism studies are required for marketing approval, and metabolites must be identified and their pharmacological activity as well as their toxicological potential must be assessed [25]. In addition, the CYP450 isozymes involved will be identified, including whether the drug induces or inhibits their activity, and based on the collective information obtained, whether there is a potential for a drug–drug interaction in the therapeutic setting of the targeted population. Thus, the early elucidation of the metabolic pathway can be an important consideration to the overall development program.

The determination of the extent of plasma protein binding in rats, dogs, and humans is also important in these early drug dispositional studies. Only the free fraction of a drug is available for metabolism and excretion, pharmacological activity, and binding to tissues. The determination of the extent of protein binding (i.e., the free fraction of drug) over a concentration range that encompasses and exceeds the TK and clinical PK range is conducted in animal and human plasma. Whether binding is concentration dependent/independent can provide insights as to the activity and/or toxicity seen; determining the main carrier proteins of the drug [albumin, alpha-1 acid glycoprotein (AGP)] in the systemic circulation may have a relevance in certain disease states.

A tabulation of a nonclinical program in early development that supports continuing development is provided in the next two tables. The GLP status, the amount of drug needed, and a usual time from start to final report are presented. As development continues, an NDA-targeted toxicology program would include subchronic, reproductive, chronic toxicity studies including *in vivo* carcinogenic studies in two species.

Study	GLP status	Drug needed (g)	Time of start to final report
<i>Analytical/Bioanalytical</i>			
HPLC assay for dose verification	Y	10	One week for development and validation; Four weeks for report
LC/MS-MS for drug concentrations in rat plasma (for TK and PK)	Y	1	Four to six weeks for development and validation
LC/MS-MS for drug concentrations in dog plasma (for TK and PK)	Y	1	Four to six weeks for development and validation
LC/MS-MS for drug concentrations in human plasma	Y	5	Four to six weeks for development and validation
• Acute oral toxicity in rats	Y	50	Three to four months
• Acute oral toxicity in rats with necropsy and clinical path	Y	50	Three to four months
• Acute oral toxicity in dogs	Y	100	Three to four months
• Ames test with/without S9 activation	Y	2	Six weeks
• Chromosomal aberration (CHO test)	Y	5	One month
• <i>In vivo</i> mouse micronucleus	Y	10–15	One month
Study	GLP status	Drug needed	Time of start to final report
QT interval prolongation in conscious dog	Y	50 g	Four weeks in life, four weeks for report
<i>In vitro</i> hERG assay	Y	100 mg	Three to four weeks to QA'd draft report
Behavior in rats (Irwin test)	Y	1 g	One week in life, three to four weeks for QA'd draft report
Respiratory effects in rats	Y	1 g	One week in life, three to four weeks for QA'd draft report
Two-week oral toxicity/TK in rats	Y	300 g	Two weeks in life, six to seven weeks for QA'd draft report
2-Week oral toxicity/TK in dogs	Y	1 kg	Two weeks in life, eight week for QA'd draft report
Four-week oral toxicity/TK in rats	Y	500 g	4 weeks in life, 12 weeks for QA'd draft report
Four-week oral toxicity/TK in dogs	Y	2.2 kg	4 weeks in life, 12 weeks for QA'd draft report

(continued overleaf)

(continued)

Study	GLP status	Drug needed	Time of start to final report
IV/PO single-dose PK in rats	N	2 g	Five to six weeks
IV/PO single-dose PK in dogs	N	15 g	Five to six weeks
Protein binding in rat, dog, and human plasma	N	250 mg	Four weeks
Metabolic profile, rat, dog, and human liver microsomes	N	100 mg	Five to six weeks

4.5.3 Biopharmaceutical Considerations

BP, the use of PK to evaluate dosage forms, is an integral part of clinical development. In preclinical toxicology/safety studies, the dosage forms are not as complicated as they are for clinical use. However, the issue of dose selection is of importance, in that a dose–toxicological profile that, will hopefully, reflects what will be found in humans will be obtained. Thus, a good prospective projection regarding safety in humans based on preclinical systemic exposure would use both BA and BP principles in animal studies to ensure that the dosage/dose administered results in the maximum drug release profile [26].

Biopharmaceutical and BA studies are more complex for animal studies, and a maximal drug release profile should be determined in order to define the line between pharmacology and toxicology. To this end, the BA of the dosage form should be determined to confirm that the presence or absence of a toxic or pharmacologic effect is real and not a result of a low or no drug absorption (brick dust). In this context, ADME studies (including IV administration) and the use of *BP screens* in dogs and primates to evaluate the dosage forms for toxicology studies are very useful and have been presented earlier.

4.5.4 Go/No-Go

Usually, Go/No-Go decisions are used in the context of clinical studies. In the context of nonclinical development, toxicity in the animal safety studies in early development is the main reason for failure. Thus, it is important to ascertain a maximum drug release profile (TK) in early development. This is especially true if the toxicity found is organ specific or by an unknown mechanism. When a well-defined dosage form administered at 1×, 3×, and 10× of the projected human dose does not result in safety margins of $\geq 3\times$, the development should normally not go forward.

In early development, Go/No-Go decisions are not based on testing/evaluations of a single compound. In practice, depending on the resources, multiple NCEs are evaluated and the most advantageous are selected and brought forward for further development. It is usual that development proceeds for two to three candidates in parallel to expedite further development into the pre-IND stage. A low initial BA is not a *show stopper*, and BP considerations are evaluated to determine if the low BA is an intrinsic property or the physicochemical property of the drug substance. Thus, early development evaluates absorption as a function of dosage forms with micronized drug (reduced particle size),

various salts, or esters and routes of administration to obtain maximum absorption. Although pharmacological activity may not be uncovered and if shown not to be correlated with an extent of systemic exposure, further development could proceed at an accelerated pace.

Other factors that result in failure at the preclinical stage of development are summarized in the following table.

Toxicity	In one or more species Insufficient safety margins
Pharmacokinetics	Long or short half-life Nonlinear kinetics
Low bioavailability	Insufficient systemic exposure
Metabolism	High first pass CYP induction or inhibition
Instability	Short shelf life of product Instability of substance in biomatrices
Complex/costly synthesis	Low yield Difficult scale-up Unacceptable impurities in final product

It should be pointed out that there are caveats linked to the therapeutic target where some of the above factors are not pivotal. A long or short terminal elimination half-life may not be a show stopper: a long half-life would not be appropriate for a centrally acting drug but could be advantageous for an antiarrhythmic drug. Even if there is a high first-pass effect, depending on the targeted therapeutic area, this may not be problematic providing the drug does not have a very narrow therapeutic index (TI) and is not highly variable. However, if the first-pass effect is concomitant with a high systemic metabolism, it may be prudent not to go forward with development. Thus, detrimental results have to be evaluated and understood, and rather than a “No Go” point, it may be a “Slow Down” point, as in some cases, the detrimental results can be overcome with a good therapeutic agent brought ultimately to market. In this context, a phased approach has been proposed to facilitate a smart approach to development [27].

4.6 CLINICAL PHARMACOLOGY

It was stated earlier that basic research has used today’s technology to advance the understanding of disease(es) to new levels, which has resulted in a vast array of new NCEs to be translated into new drugs that improve patient health and management. However, in spite of all the advances on all fronts of the “medicinal sciences”, the successful transition/translation of discovery to a new therapeutic entity on the market is still not a routine process. It is our proposition that clinical pharmacology may be a foundation for the effective translation/transition of research and development to effective and safe medicines [28].

It goes without saying that drug development of a NME is not for animals but for humans; however, drug development starts with animal studies. Up to this point, an overview of animal nonclinical studies that have been outlined were presented in the context of determining a safety profile in animals that would support a first study in humans and thus continue development by conducting studies that collectively constitute clinical pharmacology essential for an NDA-targeted development.

In the simplest terms, clinical pharmacology can be defined as a qualitative and quantitative assessment of drug action once it enters the systemic circulation: an understanding of what the drug does to the body and what the body does to the drug. In the drug development process, these are studies in humans, single-dose and/or repeated-dose studies of short duration from which come the quantitative measurements of pivotal drug disposition. These first human studies are designated as phase 1 and are the learning phase for effective patient management, that is, safe and effective therapeutic use. These are usually conducted in normal subjects, although the use of patients may not be excluded. In general, exposure is limited to small numbers of subjects and safety/tolerance is always a looked-for outcome, whereas efficacy is not.

Clinical pharmacology has been a part of drug development for the past 30 years. In the recent past, there has been a trend to reduce the number of PK studies contained in an NDA submission to those considered to be essential, that is, BA, bioequivalence (BE), and dose proportionality, thus reducing unnecessary exposure to drug in healthy human volunteers. It was considered by some that these phase-1-type studies are not needed in depth as the NDA is approved based on the pivotal phase 3 safety and efficacy trials. In addition, PK studies not included in the NDA would/could be conducted as phase 4 commitments. More recently, the FDA has placed a new emphasis on PK/phase 1, as such studies are learning studies that provide understanding of drug disposition and thus being important to patient management. This can be attributed to the emergence of factors, such as race, gender, age, disease state, and administration with food, that can alter the PK–drug exposure profile and thus have an important impact on dosing regimens. This emphasis on clinical pharmacology/PK/BP and their importance to patient management is shown by the clinical pharmacology guidance documents issued by the FDA with recommendation that the results of clinical pharmacology studies should be included in the NDA and thus in the label. PK/BP studies are an integral part of the NDA and enhance an understanding of the drug in the therapeutic setting in addition to providing basic drug disposition information even those that may be conducted postmarketing (phase 4) to fill a gap.

It should be kept in mind that approval/approvability does not necessarily remove phase 4 commitments. Having some data that retrospectively addresses factors that affect drug disposition is not the same as formal studies designed to elucidate aspects that, today, are part and parcel of clinical pharmacology. Approval can be obtained, but what usually suffers is the label. In this context, it is worth remembering that a strong/complete label at approval will have a positive impact on marketing. The successful completion of phase 4 studies three to four years after approval has little impact other than fulfilling a regulatory requirement. In addition, at that time the argument may arise as to “why pay a \$200,000–\$300,000 fee for a labeling supplement in addition to the study cost.”

Often the value of phase-1-type studies is overlooked as emphasis is placed on phase 2 and phase 3 studies. It is certainly true that the data obtained from phase 1 studies does not approve an NDA. The issue falls back on *approvability* relative to having approval with a comprehensive label that provides important information for patient management. In other words, having a label that can be used by marketing and that differentiates the product from the competition. It should be mentioned that most of the negotiations/issues with FDA on the final label deal with the pivotal phase 3

studies, not with phase 1 data. This is not to say that a focused package of phase-1-type studies in early post-IND will not provide information for a better phase 2 program; additional phase 1 studies can, and should, be conducted on the way to the NDA.

4.6.1 First in Humans

The duration and safety margins obtained in the early animal toxicity/safety studies determine the entry of drug into human clinical pharmacology studies. However, before such evaluations, it is of value to estimate a maximum safe starting dose (MSSD) based on the safety profile obtained from the early animal toxicity studies. In this context, although not presented in detail, the algorithm to estimate the MSSD for first in human clinical trial has been issued by the FDA [29].

Such determinations are primarily dependent on observed preclinical toxicities and administered doses. In general, toxicity should be avoided at the initial doses. The doses chosen should allow a demonstration of the tolerability and the PK profile, which are the goals of early phase 1. The major elements in the animal species are the no observable adverse effect level (NOAEL); the level for each species tested should be converted to the human equivalent dose (HED) and converted by appropriate body surface area conversion factor (BSA-CF). This conversion factor converts animal dose in milligram per kilogram to the appropriate human dose in milligram per kilogram. In general, the resultant safety factor should be at least 10-fold. The guidance document presents tables of the factors to convert animal doses to HEDs based on the body surface area, which are to be used in the estimation of the first maximum human dose.

Usually, the first human study conducted is a single oral dose (SD) tolerance study that can also provide the first window on the clinical PK disposition of the drug: parameters such as $C_{\max}$, $T_{\max}$, AUC, $t_{1/2}$, Cl/F, and Vd/F. If an intravenous form is available, conducting this study as a PO/IV crossover would yield additional information such as absolute BA and a true estimate of Cl and Vd. In practice, a parenteral dosage form is not usually available; even if available, an IV toxicology study of at least one week duration has to be performed in at least one species (rat) to support the IV human study. There may also be resistance from management for using an IV dosage under the rationale that “we are not going to market an IV dosage form.” It should be pointed out that the rationale is not to develop an IV dosage form but to provide an important PK information, for example, BA to the overall development process. Therefore, drug is typically administered orally in hand-packed capsules.

Validated bioanalytical methods for measurements of drug concentrations are essential for the elucidation of drug disposition, and their importance has been presented earlier. The early validation of a very sensitive and robust bioanalytical method specific for drug substance can present an opportunity to conduct a microdose study in early development. Microdose studies administer doses resulting in suboptimal exposure and thus do not determine the safety or efficacy; the primary objective is to determine the drugs' PK profile. As such, they are used solely as a screen for ranking the ADME properties of drug candidates [14]. Such information early in development can contribute to better candidate selection for development. The advantage of microdose studies is thus readily discerned, obtaining a window on drug disposition before implementing

formal/traditional phase 1 clinical pharmacology studies. Every drug development program is not appropriate for microdose studies. However, if and when implemented, the quality of development decisions can be improved and thus decrease the drug failure rate.

Accelerated mass spectroscopy (AMS) is a new analytical technique that has much promise in the future [30]. AMS is really not mass spectroscopy as it is generally known. In short, ions are accelerated to extremely high kinetic energies before mass analysis. The special strength of AMS is that for techniques that measure decay, it separates a rare isotope from its abundant neighboring mass, for example, ^{14}C from ^{12}C and ^{14}N from ^{14}C . To a large extent, this is still experimental and not readily in use and thus primarily for macrodose studies, but its cost prohibits larger use. Considering the advances in MS/MS technology and highly improved detection limits, AMS may not be an added value as an analytical technique for drug disposition.

Multiple dosing (MD) studies for 7 days with dose escalation can follow until a maximal tolerated dose (MTD) is achieved, that is, an observed undesirable side effect or in rare instances, a measurable therapeutic effect is observed. In addition, a dynamic response may sometimes be measured, for example, diuresis; but a PD response has to be treated with some caution as normal volunteers (NVs), not patients are used.

4.6.2 Overview of Clinical Pharmacology

The text that outline studies that are examples of clinical pharmacology programs that give guidance for phase 2/3 dosing regimens. The conduct of these studies defines a comprehensive presentation of clinical pharmacology and, ultimately, become part of the product label as the guide for general therapeutic use. The figures show examples of clinical pharmacology studies that are conducted as regulatory requirements; the sequence of conduct is neither absolute nor important and is dependent on the individual drug, the route of administration, the targeted indication, and the information obtained to that date. It is a *menu* of studies required, the order of conduct can be *choose and pick* and thus provide a rational clinical pharmacology program with impact on the design of phases 2b and 3 that results in verifiable safety and efficacy leading to marketing approval. It should be stated that the content of the figures is not new or original to the authors, although they are arranged/grouped in an order that has been found to be advantageous in past experience.

In drug development, there always is a time-line-driven push to do more with less and faster. It was stated previously that such an approach may result in an undesired outcome and ultimately, in failure of the program. The research and development staff should thus focus on their goal and the desired outcome of the development program: a favorable package insert for filing. They need to decide how to get from where they are now to where they need to be (marketing approval) in the most the efficient, effective, and shortest time as possible.

In certain instances or places a Go/No-Go study may be suggested. These studies are conducted in NVs, although studies in patients in the targeted patient population are not excluded and used where/when warranted. Details of study designs are not given in detail; but some elements of design and the specific guidance to conduct the studies are provided.

- IV/PO single-dose PK in NVs provides the intrinsic PK following the administration of dosage forms (tablets, capsules, liquids) used in the pivotal phase 1 trial

to determine the relative BA and BE [31]. Usually, these studies are conducted as an open label; single-dose crossover design with a small number of subjects (usually, 18–32) determined statistically to meet the “80–125% rule.” However, if drug variability is high and requires very large subject numbers (60–80 or more) to meet the BA/BE criteria, use of a single-dose, four-period, four-sequence, randomized, crossover, replicate study design can be used to obtain BE [32].

- Effect of single doses of high fat food on the rate and/or extent of absorption relative to the fasted state studies are a requirement that should be conducted in early development [33,34]. Although the mechanism of the effects of food is not clear, food can also influence factors such as bile flow, gastric emptying, luminal metabolism, the first-pass, and complexity with excipients, all of which can affect drug absorption. If the effect of food is demonstrated, a study on the time of drug administration relative to food administration should be ascertained [34].
- If the drug is targeted for pediatric use, the development program includes the BP of oral solutions or suspensions, dosage forms targeted for the therapeutic use by children. However, if drug development is primarily for use in adults and is/can be used by children, oral dosage forms such as capsules and tablets may present children with difficulty in swallowing. In such case, studies should be designed to determine if the tablet can be crushed and administered with applesauce. These studies are considered *food studies* and are evaluated as described above.

The guidance documents mentioned earlier address the study design, the statistical evaluation for acceptance (90 CI, the 80–125% “rule”), and the number of subjects to be used. The main objective is the respective BA and/or BE study as directly applicable to clinical use. However, the study design generates the intrinsic PK properties of the drug ($C_{\max}$, $T_{\max}$, AUC, $t_{1/2}$), and these properties are included in the data presentation. For repeated-dose studies to steady state, escalating dose MTD/tolerance studies and dose linearity studies to ascertain if PK properties are linear are used. Although there are no specific guidance documents, those mentioned above provide the rationale, study design and statistical evaluation (if needed/appropriate) as above.

An understanding of the metabolism of the drug under development is a requirement for marketing approval. It is required to identify all metabolites formed and their relative concentration (percentage of total mass). The metabolic reaction types such as phase 1 transformations can be either by the introduction of a functional group (oxidation) or by the unmasking of functional groups (hydrolysis) and are the main steps of the metabolic disposition of drug. Phase 2 transformations are primarily the conjugation reactions that result in highly polar derivatives for excretion in urine, bile, or feces. Taken collectively, metabolism studies determine the mass balance of the drug (and drug-related material), characterize the routes of elimination and drug clearance, and identify and quantify the drug remaining in systemic circulation. An additional and more detailed treatment of drug metabolism is presented below in the role of drug interaction studies.

Single-dose metabolism studies using ^{14}C -radiolabeled drug(s) are conducted in early development to ascertain the information on the presystemic metabolism, the mass balance, and the routes of elimination. The use of ^{14}C -radiolabeled drug is a proven tool for drug metabolism; however, the radiosynthesis of the drug substance is required and may, depending on the synthetic route, be costly to obtain the specific

activity required. Replacing ^{14}C with stable isotopes for the use in drug metabolism may be more advantageous [35], and this approach has been used to determine an extensive metabolic disposition of drug in the rat [36].

An important *in vitro* study considered to be clinical pharmacology is the determination of the extent of plasma protein binding to determine the free drug concentration (not to be equated to the free fraction). Included is determining whether plasma protein binding is drug concentration dependent or not and the major carrier proteins, for example, albumin and AGPs.

Clinical pharmacology studies are regulatory requirements to determine drug disposition as affected by intrinsic factors (renal and hepatic insufficiency) that compare the PK of subjects with normal organ function to matched groups of the respective impaired organ [37,38]. This evaluation is important since the liver is the main organ of drug metabolism, whereas excretion of drug and metabolites are mediated by the kidneys.

It is generally recognized that numerous drugs are metabolized by the CYP450 enzymes located primarily in the liver. Most of the drug-metabolizing enzymes are in the CYP1, CYP2, and CYP3 families. The activation and metabolism of many drugs are dependent on the enzymes of the CYP450 system and can lead to wide interindividual differences in the clearance of drugs. These differences in metabolism can alter the dose–response relationship, leading to an increase in adverse events and toxicity as well as therapeutic failure [1,2].

Of the 50 CYP450 enzymes, CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4/5 are responsible for the metabolism of $\sim 90\%$ of currently marketed drugs [39]. These enzymes are predominantly located within the liver but may also occur in the small intestine, lungs, placenta, and kidneys [39]. The CYP3A4 isozyme is very abundant and important in the metabolism of many drugs. Its presence in the gastrointestinal (GI) tract is responsible for the low oral BA of many drugs. It should be noted that nondrug substances such as grapefruit juice and herbal supplements such as St John's wort can cause significant inhibitory and inducing effects, respectively, on CYP3A4 substrates.

Of the major isozymes identified above, three have shown genetic variance in their alleles (CYP2C9, CYP2C19, and CYP2D6), which can be expressed phenotypically in patients as poor, intermediate, extensive, or ultrarapid metabolizers. Therefore, drug metabolism via CYP450 isozymes exhibits variability (polymorphism) that can influence an individual patient's response to a drug.

Genotyping for patients who receive mono- or polytherapy medication that are metabolized by isozymes that show variable individual metabolism (CYP2C9, CYP2C19, and CYP2D6) may assist clinicians in avoiding adverse drug–drug interactions and to individualize treatment with new pharmaceutical agents better. In the future, the use of genotyping to determine metabolic status of polymorphic drug-metabolizing enzymes will be integral to efficient patient care and management.

Although not all inclusive, the above outline of clinical pharmacology reiterates and confirms the role of clinical pharmacology/phase 1 and represents the learning stage of development during which an understanding of the drug and how to use it is obtained, whereas, as was stated previously, phase 2/3 uses what has been learned and confirms safety and efficacy.

4.6.3 Decision-Making Studies

As mentioned above, for some indications, certain studies can (and should) be conducted in patients rather than in NVs. Studies on drug interactions and hepatic and renal dysfunction must be conducted according to their respective guidance's. Once a drug substance is targeted for development, the expeditious conduct of a core toxicology package allows the initiation of the early clinical studies: an effective development program. It should also be mentioned that, as indicated/suggested in the figures below, many of the studies can be conducted in parallel, resulting in the overall development time line on the way to the NDA.

It has been stated previously that today PK/BP are well-defined components of drug development. There has been a progressive and increased emphasis by the FDA on the understanding of the PK and PD of drugs not only in healthy subjects but also in special populations. In this context, there is a great emphasis to evaluate and understand the potential for *in vivo* drug interactions, especially as polytherapy is the norm with an aging population. Thus, the "Clinical Pharmacology" and "Dosing Information" sections that correspond to these sections of an NDA dossier can comprise the major part of the label as the information therein is targeted to guide patient management (as an example, the labels of the two marketed cyclooxygenase 2 (COX-2) inhibitors contain the results of 17–22 drug interaction studies). On the basis of the regulatory guidance documents, pharmacology studies will provide data that are decision making as the development program moves forward. In the following sections, examples of several scenarios that illustrate effective drug development in phase 1 with inclusion of the current emphasis on drug interactions are presented in some detail.

4.6.3.1 Decision Based on Early Phase 2. This development outline is based on an early understanding of the drug as to its therapeutic value and thus continuing development.

Figure 4.2 introduces a concept that is an important contributory to the Go or No-Go decision: POC. In its simplest definition, a POC is a demonstration that a certain method (or idea) is supported by data of its feasibility and whose purpose has the potential of being used. In drug development, POC is not synonymous to proof of principle as

Figure 4.2 Phase 2a for Go/No-Go decision.

they lack clear definitions and they vary in usage between authors, investigators, and institutions and in usage over time.

In these early studies, it is usual that the preliminary dosage forms are used, for example, hand-packed capsules rather than galenic formulations. In many, perhaps, in most cases, the defined PK profile is the main objective. As/when development continues and a final dosage form is developed (for phase 1b or phase 2), a bridging BP study would be conducted relative to the initial form. The absorption PK would be compared as to the validity of the early study using a study design to determine whether the PK is linear over a projected dose range.

POC refers to early development, and the convention is to divide it into *phase 1* and *phase 2a* studies. Phase 1 studies are usually small ($n = 10\text{--}20$) single-dose studies in healthy volunteers; a short course of repeated doses (one to two weeks) can be conducted. A single-dose study determines whether the desired PK profile is achieved and the tolerance of the administered dose; with repeated doses, a signal for the desired clinical activity may be an outcome. At this stage, a Go decision implements the ADME studies required for complete development. Phase 2a is usually conducted in up to 100 patients to ascertain tolerance/safety and pharmacological activity and select a dose for the NDA-targeted studies.

The above panel outlines a series of studies that would allow the conduct of a POC study, the results of which determine the Go/No-Go decision.

The underlying principle for the POC concept is related to the use of biomarkers and surrogate end points in early clinical trials. This is a very extensive topic and, in fact, is the subject of not only research publications but also entire books; as such, only an introduction of the topic can be accommodated. In simple terms, a biomarker is a substance whose detection has been shown (validated) to correlate with the detection and/or progression and treatment of a disease. In clinical research, a clinical end point is a sign that defines a target outcome of a study. In this context, early drug development programs include investigations to identify and validate biomarkers to ascertain a Go/No-Go decision. In fact, the search for biomarkers is increasing and is now part of drug development in general. The scope and intent of this chapter can only be introductory in nature as a full treatment would warrant its own chapter.

However, it is necessary to distinguish between *disease-related* and *drug-related* biomarkers. Disease-related biomarkers indicate a probable effect of treatment in case(s) if/when the disease already exists. Drug-related biomarkers indicate whether a drug will be effective. At present, there is much effort in the discovery and development of innovative and effective biomarkers; these new biomarkers have become the basis of preventive medicine. However, it should be noted that even though a process can be repeated, it may not mean that it is true; thus, a new biomarker should undergo a rigorous validation.

Even when validated, in a clinical trial, meaningful outcomes based on biomarkers can be expensive or impossible to achieve. In this context, surrogate markers/end points that measure the effectiveness of treatment are used especially when these correlate with a real clinical end point. It is a measurement that is easier to assess than the true end point.

In essence, a surrogate marker (or end point) is a measure of effectiveness, as it is intended to substitute for a clinical end point. Surrogate end points often occur after an intervention in the disease process and can be an effective substitute. As with

Figure 4.3 Efficient early drug development.

biomarkers, validation is a critical factor. For validation [40] as an end point, these conditions are to be met: (i) evidence that the surrogate predicts the true end point; (ii) end point must be specific, for example, the intervention is mediated via the surrogate end point; and (iii) all information on adverse effects associated with the intervention must be captured.

Thus, it is efficient to conduct a POC study as soon as possible, even though the animal toxicity studies indicate good safety margins for human studies; without efficacy, there is no need for further development.

Assuming that the POC study clearly indicates efficacy, development would enter phases 2a and 2b with studies in the targeted patient population in order to determine the dose(s) for the pivotal phase 3 studies.

Considering that conducting clinical pharmacology studies are not dependent on the final clinical dose, many studies can be conducted in parallel to phase 2. In this case, the sequence of conduct impacts efficiency. This is illustrated in Figs. 4.3 and 4.4, which present the sequence in a somewhat different manner.

There are occasions when the data in early development support a Go decision for further development, but for a variety of reasons, the decision is made to out-license the drug. Again, if there are no safety concerns from the animal toxicity panels conducted, interest to in-license the drug would depend on the clinical studies conducted. A suggested scenario with single-dose human data is shown in Fig. 4.5.

In the development program presented above, the goal was to obtain an open IND and to enter phase 1 clinical development. The above chart presents a program where the objective is to bring the development forward to the stage where out-licensing could be an option.

The above scheme would be greatly facilitated by the *in vitro* determination to determine how metabolism occurs using rat, dog (the toxicity species), and human liver

Figure 4.4 Efficient development to NDA.

Figure 4.5 Single-dose proof of concept for licensing.

microsomes. This experiment would also identify the CYP450 isozyme(s) involved in metabolism and thus provide information as to a drug interaction potential if development continues. The availability of ^{14}C drug product at this time would greatly facilitate the determination of mass balance (and metabolism); however, using cold assays and collecting urine and feces in the SD study, in addition to plasma, would provide a reasonable preliminary determination of the mass balance without the additional expense of ^{14}C synthesis. However, this would need to be performed once a Go decision is reached after phase 2a.

Out-licensing can also be facilitated by the conduct of repeated-dose clinical pharmacology studies. An outline of such an approach is shown in Fig. 4.6.

Figure 4.6 Proof of concept for licensing.

The advantage of a positive POC is self-evident. However, the availability of steady-state PK from the multiple-dose study would be an added attraction as such would have an impact on phase 2 studies in the targeted patient population.

4.6.3.2 Radiolabeled Studies (ADME). The conduct of a single-dose PK drug disposition study (ADME) is a powerful tool in development, especially when conducted early in the development process. A study with ^{14}C drug and the collection of serial plasma samples over a dosing interval can provide a qualitative window on the extent of metabolism from the respective slopes of total radioactivity relative to cold drug. Also, the AUCs of the total radioactivity relative to the cold drug can provide additional information, for example, elimination half-life of both moieties. In addition, from concentration–time data in urine and feces, the major routes of elimination and thus a mass balance can be obtained. Under ideal circumstances, a study in six NVs would be conducted using both IV and oral dosing in a crossover manner; the duration of sampling time would be monitored for radioactivity until the radioactivity is at LOQ. It must be stated that it is a regulation that a rat dosimetry study *must* be conducted to obtain an estimate of the residence time of the radiolabel and the conduct of human study must be approved by government of the state where the study will be conducted.

The challenge of an ADME study is the availability of the ^{14}C drug of sufficient purity and a high enough specific activity for accurate quantitation. There may be resistance to the cost of the synthesis, but it should be pointed out that once available, the radioactive drug can/will be used for required rat tissue distribution and plasma protein binding studies. In addition, in the case where the most appropriate animal species for the pivotal toxicology/safety evaluations is not evident, a radiolabeled study in several species (dog, monkey) would be conducted. By comparing radioactivity concentration in plasma, urine, and feces, it can be estimated which species approximates humans in metabolism and PK.

4.6.3.3 Role of Metabolic Disposition Studies. The role of metabolism in the overall process was mentioned previously. In general, drug metabolism (biotransformation) occurs as two categories: phase 1 and phase 2 reactions. Phase 1 reactions are nonsynthetic reactions and include oxidation, reduction, and hydrolysis. These reactions are

mediated by the CYP450 located primarily in phospholipid bilayer of the smooth endoplasmic reticulum and most of the organs in the body. Phase 2 reactions are synthetic biotransformation reactions that *link*/conjugate the parent drug or a phase 1 metabolite with an endogenous substance. These reactions include glucuronidation, sulfation, acetylation, methylation, and other conjugations. Taken collectively, the purpose of metabolism is to convert the exogenous lipophilic drug to water-soluble metabolites that are readily excreted from the body.

Formal studies to identify the major metabolite(s) in the systemic circulation—the number of metabolites formed *in vivo*, their structure, and whether any of the metabolites have a pharmacological activity; the routes of elimination; and a mass balance—constitute a more comprehensive role for metabolism in drug development. An important outcome of such evaluations is the elucidation of the metabolic pathway of a drug in humans and also in animals.

It is important to the understanding of the drug to determine the site of metabolism (hepatic, presystemic) and the specific member(s) of the CYP450 family of isozymes that mediates the metabolism. The identification of the specific CYP that is responsible for metabolism is virtually mandatory, especially as some isozymes have overlapping activity. The ability of the drug to inhibit or induce a member(s) of the CYP450 family *in vitro* is an important study that has downstream implications on drug–drug interactions potential *in vivo* in the clinical setting; specific protocols for such studies and when such studies need to be conducted can be found in the FDA and ICH guidance documents. It should be noted that these studies should be conducted earlier rather than later, especially if more than one isozyme contributes to the metabolic disposition of the drug. When metabolism occurs via multiple isozymes, clinically significant *in vivo* drug–drug interactions are less likely to occur (also see Section 4.6.3.4). What is more important to understand is the involvement of multiple isozymes rather than all possible outcomes.

In Figures 2–6, individual studies are presented as line items that, when taken in the collective, illustrate the mosaic defined as early drug development. As a collection of line item studies, it is natural to see the total, and thus easy to overlook one of the line items in terms of its importance to the whole. Thus, although drug–drug interactions are depicted in one line, their importance greatly exceeds their presence in drug development schemes. Today, the understanding of drug interactions with another drug administered concomitantly is an essential part of drug development, especially in polytherapy. It is prohibitive, and not the intention of this report, to recite drug–drug interaction presenting data of specific examples. The intention is to present key elements of drug interaction studies as a process, with study design based on the regulations as they apply to a specific drug and/or therapeutic area.

4.6.3.4 Drug Metabolism–Drug Interaction: *In Vitro* Studies. Once in systemic circulation, the process of a drug's elimination is initiated either by excretion intact in urine or feces or, primarily, by biotransformation (metabolism) [41]. If/when metabolism is the main process, the metabolic routes(s) are of importance as they can significantly affect the safety and efficacy of the drug. If elimination is via a single pathway, individual differences in the metabolic rate(s) can lead to significant differences in systemic concentrations of drug and/or metabolism as a consequence of activities of the CYP450-mediated metabolism. This metabolic pathway may be relatively simple or may be complicated by the involvement of multiple and

concomitant cytochrome isozymes with additional complexity added if these exhibit bimodal distribution because of a genetic polymorphism. For these reasons, it is important to learn the early stage of development in the metabolic route if the drug is eliminated primarily by metabolism and to ascertain its route of elimination. If metabolism is the primary route, it is important to identify the specific CYP450 isozyme(s) responsible for the drug's biotransformation.

The most prevalent site of drug metabolism is the liver. The most mature technology for the *in vitro* determination of hepatic drug metabolism is the use of human liver microsomes. Using selected commercially available CYP450 inhibitors for specific pathways, the metabolic pathway can be either demonstrated or ruled out. Once a pathway has been determined, the metabolic pathway can be confirmed using recombinant human proteins. Human liver microsomes are also used in assessment of a drug–drug interaction by concomitant incubation(s) using a concentration of the test drug and a standard test probe compound. A complete evaluation in detail is not the purpose here, and such a treatment is found in Ref. 41. It is also important to point out that *in vitro* studies do not adequately define the metabolic pathway and should be subsequently verified in a clinical study.

4.6.3.5 Drug Metabolism–Drug Interaction: *In Vivo* Studies. Current therapeutics seldom involve monotherapy, as the general population is older and whose treatment utilize multiple drugs on a daily basis [42]. The physiological changes in metabolism associated with aging increases a potential for an occurrence of drug interactions.

Not every drug–drug interaction is metabolism based. Changes in PK due to absorption, plasma protein binding, distribution, and excretion can be a mechanism for drug interaction. Thus, any drug interaction should be adequately assessed in the overall assessment of drug safety and efficacy. In this context, all drug–drug interactions are only relevant when a drug's metabolite(s) have been identified and their pharmacological properties elucidated. And only then, an understanding of the relation of specific drug(s) may emerge as a relationship between *in vitro* and *in vivo* is evaluated.

The potential for a drug–drug interaction is first evaluated *in vitro* by identifying the CYP450 isozyme(s) involved in its metabolism using proper studies designed for this purpose. Once identified, separate studies are conducted to assess the potential for its induction or inhibition and whether the outcome is a linear process. A clinical study is then used to determine the effect on disposition of the drug in question. Whether the uncovered PK changes are clinically significant is determined by the TI of the drug: if the TI is large numerically, changes of even 50% are not significant; however, if the TI is narrow, 10% changes can be significant in the clinical setting.

In general, *in vivo* drug–drug interaction studies compare concentrations of the drug to be evaluated (substrate, S) to determine if its exposure is changed relative to another drug that is interacting (interactant, I). A study can be conducted by several crossover designs and several combinations of single–repeated doses. The above mentioned guidance document provides various study designs, depending on the drug and study objective. One objective of the study design that needs to be kept in mind is that inhibition or induction needs to be evaluated as the end point. In general, induction takes longer to be ascertained, whereas inhibition is attained relatively more rapidly. In addition, the outcome sought may be concentration dependent: the induction of CYP3A4, the most prevalent hepatic isozyme accounting for ~ 40% of hepatic

mass, is both concentration- and time-dependent inductions [43]. In most cases, inhibition/induction drug interaction evaluations are conducted as single-dose studies; if done at steady state, data to document such is needed.

Clinical drug–drug interaction studies are/may be conducted using healthy volunteers. Safety considerations should always be carefully evaluated if the desired outcome may preclude their use because of not knowing if the drug’s metabolism is a result of polymorphism. In current drug development, it is not uncommon to determine a subject’s phenotype or genotype before study conduct. To characterize a drug as to its potential to be an inducer or inhibitor, the establishment of which CYP isozyme(s) is involved in its metabolism is desired as quickly as possible.

PK end points with studies at maximum or approved doses should be evaluated. Parameters to be assessed include AUC, $C_{\max}$, and time taken to attain $C_{\max}$; PK parameters are clearance, volume of distribution, and half-lives. The exposure parameters are reported as 90% confidence intervals of the geometric mean ratio of the PK measures with and without the interacting drug. The guidance documents [42] is important, as it presents not only specific aspects of study design but also data evaluation.

The importance of understanding drug–drug interactions and its role in therapeutic drug use has resulted in the development of surrogates using *Escherichia coli* for a rapid characterization of CYP450s 1A2, 2C9, 2C19, 2D6, and 3A4; these surrogates agree well with corresponding human hepatic isozymes in literature, and thus indicate that such recombinant isozymes may be of value as predictive human metabolism [44].

4.6.4 Drug–Drug Interactions: on the Way to the NDA

The drug–drug interaction studies in early development, by large, can be considered as monotherapy and as such determine the basic foundation of how/when interactions occur: the studies are designed to produce an interaction. A goal in development is and should be to learn the drug disposition, to understand the drug under development, and then to apply this knowledge for successful therapeutic interventions in a large diverse population. Today, monotherapy, although desired, is relatively rare. This is especially true as the general population is elderly and uses multiple therapeutic agents on a daily basis. Thus, as stated above, it is very important to evaluate and understand contraindications of concomitant drug use as the resultant adverse or serious adverse reactions can occur. If the prevalence of these adverse reactions is considered serious with some incidences of death, the drug may be *pulled* from the marketplace.

The identification of which CYP450 isozyme(s) is responsible for the drugs metabolism, whether it can be induced or inhibited, cannot be overemphasized, especially as several CYP isozymes, (e.g., 2D6, 2C9, and 2C19) show a bimodal distribution because of genetic polymorphism. Polymorphism can affect the metabolic route of elimination and alter the systemic plasma concentration profile of the drug, with a consequence requiring dose adjustments to maintain safety and/or efficacy.

The common use of pharmacogenetics (genotyping of patients) already influences therapeutics: for Caucasian patients, ~ 7% cannot metabolize drugs that are primarily metabolized by CYP2D6. Similar information is being uncovered for CYP2C9, CYP2C19, and *N*-acetyltransferase. CYP3A4 activity is involved as the primary isozyme in the metabolic disposition of many drugs, both systemically, as it is the most abundant hepatic enzyme, and pre-systemically (during the absorptive process).

When the role of CYP3A4 is established, a drug interaction with ketoconazole (a strong inhibitor of CYP3A4) is conducted to evaluate the effects on the $C_{\max}$ and AUC of the drug; effect–no effect is established by 90% confidence interval, the 80–125% rule.

A current understanding of all factors that impact on metabolism-based drug–drug interactions is available as a guidance document [45], although as a draft. This guidance combines the salient aspects of general factors for the evaluation of clinical drug–drug interaction but of more importance, presents a comprehensive and extensive treatment of all current knowledge of metabolic drug interactions. This information is presented in tabular form and includes current summary of data from recently conducted trials. Such a comprehensive treatment of drug interactions is not in the scope of the present report but is presented to as a continuum and references what can/should be used as the development process continues.

To this end, an overview of some new aspects of development, especially in drug–drug interactions are briefly presented since they are an indication of the direction of effective development being implemented now and refined in the future.

- The pivotal role of CYP3A4 as the most abundant hepatic and intestinal isozyme that metabolizes half of the drugs on the market will be evaluated in development programs of new drugs to determine if drugs are substrates, inhibitors, or inducers of this pathway [46].
- Substrate specificity and regulation of drugs that exhibit polymorphism of their expression, especially of isozymes that are considered to have a low level of their expression will be included in routine drug–drug interaction studies [47].
- The role of transporters will be elucidated to provide advancement to the critical path of drug development [48,49].
- The use of drug cocktails in the conduct of drug interaction trials assist in clearly defining drug interactions in the clinical setting [50–53].

The above represents current advances in technology that have been, and continue to be, incorporated into current drug development, resulting in better therapeutic outcomes.

4.6.5 Past “on the way to the NDA”

Most of the concepts previously presented were targeted for early drug development to support safety and efficacy, especially in drug disposition as the learning process to a successful marketing approval. As such, they are set pieces aimed to open an IND, contribute to the design of the phases 2 and 3 studies, and if/when a successful NDA is achieved, provide specific guidance to the safe and effective management of patients, which is the label. Thus, it is worthwhile to revisit the process as a whole presenting the end of drug development as it is condensed into a primer for patient management.

4.6.6 The Label

A general outline of the studies that would contribute to the final label (Package Insert) has been presented previously. The presentation order of the information in the label

can vary with the drug and the content of the development program. There is, however, a general format that is followed and this is (in part) given below.

Description of the drug product listing the dosage form(s), a brief galenic composition and available strength(s) is usually presented first, followed by the structure, molecular weight, chemical name, the empirical formula, and its appearance and solubility.

Clinical pharmacology: These are the phase 1 single-dose studies in NVs, although repeated-dose studies and using patients are not excluded. Studies dealing with BA; BE; food effects; effects of age, gender, and ethnicity; and the dosing regimen(s) are presented with the appropriate metrics.

Mechanism of Action: The targeted indication is then given with a short summary of the key elements that describe the activity of the drug in the indication.

Pharmacokinetics: The systemic moiety (parent drug and/or metabolite) that affects the activity is then stated. The key PK parameters ($C_{\max}$, $T_{\max}$, AUC, $t_{1/2}$, CL, and V) in NVs and targeted patient population following oral and, if conducted, intravenous administrations are presented. Intra- and intersubject variability is addressed in the context of a dosing regimen. The PK sampling compartment (blood or plasma) is given.

Absorption: The extent of absorption (percentage of relative and/or absolute BA) in the target patient population and NVs is given. If there are different strengths and dosage forms (e.g., 5 mg tablet and 10 mg capsule), the BE of these is determined. If the patient dosing regimen involves several doses, the linearity of the systemic exposure as based on the correlation of the doses to $C_{\max}$ and AUC is determined.

Food Effects: The rate and extent of absorption are tested under fasted conditions and compared to the same when the drug is administered in the presence of food. A high fat meal (850 kcal, 46% fat) is the meal tested. If significant, the effect of the high fat meal is compared to a high carbohydrate meal (680 kcal, 85% carbohydrate) relative to the fasted condition. The presented effects are significant relative to a clinical setting are thus described with the addition of the results of the time of food administration relative to drug administration (2 h before, with drug, or 1.5–2 h after the meal). Taken collectively, the food effects are an implicit recommendation for patient management.

Distribution: In very early development, the partitioning of the drug between blood and plasma should be established to ensure that the right compartment for PK is sampled. The extent of plasma protein binding of the parent drug and its major metabolites should be determined *in vitro* by equilibrium dialysis and compared to that in *ex vivo* plasma samples, especially in special populations (renal, hepatic insufficiency). The following should be ascertained: is binding concentration dependent, the contribution of carrier proteins (albumin, AGPs) as their concentration in plasma can change in disease states. If the extent of binding is high (>98%), it should be remembered that even small changes in the free fraction (Ff) can have a large effect on drug disposition.

Metabolism: The extent of metabolism as well as identifying the CYP450 isozymes is presented. The identity of the metabolites, especially the major metabolites, is given with *in vitro* results compared to *in vivo* results. A metabolic pathway is

proposed. The metabolic profile is important to considerations of a potential for drug–drug interactions as was presented above.

Excretion: The routes of elimination (urine, bile/feces) are determined and quantitated, and a mass balance estimation is given. Usually, this is conducted using the ^{14}C drug, although cold assay can be used but may present a challenge in terms of recovery and resolution of drug from noise.

Special Populations: The parameters of exposure (AUC and C_{max}) as well as $t_{1/2}$, V , and CL are determined in patients with renal and hepatic impairment and compared to subjects with the respective normal function.

Issues such as effects of race/ethnicity and gender on drug disposition are addressed as specific stand-alone studies, but such information can also be obtained from the phase 2/3 studies.

Nonclinical studies that impact on safety are also in the label: carcinogenesis, mutagenesis, and reproductive toxicity, which form the basis of the pregnancy category. These studies were stated previously in the outline of the nonclinical studies that are conducted as part of the toxicity/safety evaluations; the study design and resultant evaluations are given in their respective guidance documents.

4.7 SUMMARY AND CONCLUSIONS

When all is said and done, drug development is a costly and time-consuming process; there are no *shortcuts* in spite of a detailed road map and experience. Although the same outcome is desired in principle, each drug and its development process is different in specifics, cost, total development time, and more importantly, regulatory acceptance. If the development is successful, the end product is a dossier of study reports conducted that present a convincing conclusion that based on data, the drug is safe and efficacious and warrants approval to market. In this context, there is always pressure for efficient drug development implying the unspoken caveat meaning “do it quicker” or “less costly” or “be smarter.” However, the appropriate description should be effective for this characterization encompasses the process in terms of where it was, where it is, and where it is going, specifically, marketing approval.

It is not the intent of the present report to be all inclusive; in fact, this would not be possible because of pragmatic limitations. We have concentrated on segments in early development that present rationales to move development forward with the caveat that the bulk of development is conducted “on the way to the NDA.” Whatever variations in timing and procedures an individual development undergoes, safety and efficacy should never be lost in sight and should be demonstrated by data. Data using rational study designs and flexible study conduct sequences that provide information for Go/No-Go decisions are essential. In other words, an effective development program in which core nonclinical safety studies enable an open IND and is followed by the first human studies (phase 1, clinical pharmacology), which provide the learning tool for information on the drug. As development continues, what has been learned is confirmed in phase 2 and phase 3 and the safety and efficacy of the drug in the context of the dosage and dosing regimen established.

Figures 2–6 that outline several phase 1 scenarios are examples of an effective phase 1 process and are not singular in that these and their variations have been found to be of use by the authors (and others) and are thus given as examples. As shown, it is important to ascertain the drug release profile as an evaluation of the dosage form, the extent of systemic exposure and assess factors that can influence absorption (i.e., food). As a general consideration, mass balance, routes of elimination, major metabolite identification, and the elucidation of the metabolic pathway must be confirmed. Considering that today's polytherapy is the norm in an aging population, the identification of the key metabolites and the CYP450 isozyme(s) mediating such metabolism is essential. Whether these are induced or inhibited is mandated to understand the potential for a clinically meaningful drug–drug interaction(s) and is mandatory for effective patient management with safety and efficacy.

On the basis of today's knowledge, the role of polymorphism in determining drug interaction potential and role of transporters as substrates and/or their induction/inhibition potential are a major part of drug development. It is likely that the ability to understand the overall disposition of drugs, especially metabolism in current terms, will in the future result in individualized therapeutic regimens.

ACKNOWLEDGMENTS

Dr. Bekersky wishes to acknowledge the late Dr. Wayne Colburn for discussions they held over the years on drug development. Many of the concepts from those discussions are presented herein.

5.1 INTRODUCTION

Among the experimental activities carried out in pharmaceutical research and development organizations that are associated with absorption, distribution, metabolism, and excretion (ADME) sciences, the elucidation of the chemical structures of drug metabolites (addressing the “M” in ADME) is probably the most mature. In fact, many modern drug metabolism-pharmacokinetics (DM/PK) or ADME departments originated as drug metabolism groups assigned with the task of identifying the main metabolites present in excreta samples from laboratory animals and humans. Nevertheless, despite its maturity, the field of drug metabolism and metabolite identification has changed considerably and continues to be dynamic, not only in the techniques and technologies applied in conducting the laboratory work but also in the scope of questions being addressed in pharmacology, medicinal chemistry, and toxicology with drug metabolism information. In this chapter, modern techniques of structure elucidation of drug metabolites are described. These include mass spectrometry (MS) and nuclear magnetic resonance (NMR) spectroscopy. Sample generation and workup procedures are also described, as well as some special techniques applied to elucidating structure. However, before describing these technical aspects, this section outlines the utility of metabolite structure elucidation in drug research.

5.1.1 Metabolite Structure Elucidation in Drug Discovery

The drug design process is an arduous one because it requires the simultaneous optimization of multiple properties, and in many cases, structural modifications that

improve one property will be to the detriment of other properties. For example, it is generally the case that target receptor affinity and selectivity can be increased by adding substituents to a structural backbone. However, it is also generally the case that the addition of these substituents will lead to declines in ADME properties, such as increasing metabolism or decreasing membrane penetrability. Thus, ADME scientists, as well as the subset of those scientists who specialize in the elucidation of metabolite structures, need to be working contemporaneously and in collaboration with medicinal chemists and pharmacologists charged with designing a new drug. In the drug discovery phase, the type of knowledge gained from metabolite structure elucidation can be leveraged to enhance the design of new drugs by

1. aiding in decreasing metabolism, which can yield drugs with lower clearance, longer half-lives, and increased oral bioavailability;
2. determining the main routes of metabolic clearance and, by identifying the type of metabolic modification, suggest which types of enzymes may be involved in these metabolic routes;
3. identifying routes of metabolism that yield chemically reactive intermediates that could cause toxicity; and
4. identifying metabolites that may possess pharmacological activity similar to the parent molecule and contribute to pharmacological effect.

These are described below.

5.1.1.1 Decreasing Metabolic Lability. In many drug discovery programs, the problem of high clearance is encountered. If one considers that the existence of xenobiotic-metabolizing enzymes in organisms is to prevent foreign materials encountered in nature (through purposeful or accidental ingestion) from entering and residing within the body and its vital organs, then it follows that a challenge will exist in trying to achieve bioavailability of foreign drug molecules. Most of the high metabolic lability of drugs is because of cytochrome P450 and glucuronyl transferase enzymes, which are highly abundant in liver and intestine. Many drug research programs now routinely test newly synthesized compounds in screens of metabolic lability in human liver microsomes supplemented with cofactors necessary for P450 catalytic activity. From screening, some insights to structure–activity relationships regarding metabolic lability can be gleaned in some cases; however, this can be challenging since multiple P450 enzymes could be responsible for lability observations.

To reduce lability caused by P450 enzymes, the determination of structures of metabolites can be highly informative. This can permit the introduction of chemical substituents associated with greater resistance to metabolism at positions of the chemical scaffold that are identified to be susceptible to metabolism. Small, directed modifications will also be less likely to disrupt the affinity for the target and they will not substantially change the physicochemical properties that direct the overall distribution properties of the compound. If the actual labile substituent cannot be removed because of its importance in target-binding activity, there are other approaches to reducing metabolic lability, which include sterically disrupting the interaction between the labile site and the active center of the heme of P450 or introducing substituents that alter the electronics of the metabolically labile site. Depending on the type

of metabolic reaction being catalyzed, P450 enzymes act by abstracting hydrogen atoms (e.g., aliphatic hydroxylation and *O*-dealkylation reactions) or electrons (e.g., *N*-dealkylations and aromatic hydroxylations) from their substrates. For hydrogen atom abstractions, replacement of the hydrogen with a nonabstractable atom, such as fluorine, is a common strategy to introduce metabolic stability. Electron abstractions are usually more difficult to reduce, and alterations of the electronics of the substituent or building steric bulk around it are most frequently attempted. Placement of electronically linked halogen atoms or replacing methyl/ethyl substituents with *t*-butyl are commonly employed strategies. To propose any of these strategies, the site of oxidation must first be identified. In most instances, this can be accomplished by identifying the major metabolites in extracts of *in vitro* incubation mixtures using high performance liquid chromatography-mass spectrometry (HPLC-MS) and NMR as needed. These are described in later sections.

5.1.1.2 Identifying Major Routes of Clearance. In drug design, a sense of what types of clearance mechanism will remove the new drug in humans is important. Since it is desirable to engineer the clearance to permit good bioavailability and suitable half-lives, which in turn permit facile dosing regimens, the mechanism(s) of this clearance must be known. Furthermore, different types of clearance pathways possess differing degrees of interpatient variability; thus, knowledge of the main clearance pathway will aid in predicting variability in pharmacokinetics. For example, in Section 5.1.1.1, it was stated that reduction of P450-mediated metabolic lability is important. However, if the compounds being studied are actually more readily cleared by another drug-metabolizing enzyme, such an endeavor will be fruitless in addressing the real problem. Thus, the identification of drug metabolites, using either *in vivo* samples (i.e., excreta samples from laboratory animals) or an *in vitro* system that contains a nearly complete complement of drug-metabolizing enzymes (e.g., human hepatocytes) can aid in generating the knowledge of the main clearance mechanisms. In drug discovery programs, the observation of inconsistency between the clearance predicted from data generated using animal-derived *in vitro* systems and the clearance observed *in vivo* in these species will suggest that there may be clearance pathways contributing, which are unaccounted for. The elucidation of metabolite structures will lead to the proposal of such pathways.

5.1.1.3 Decreasing the Generation of Chemically Reactive Metabolites. Although there are very few cases of bona fide proven examples of drug toxicities caused by the generation of chemically reactive electrophilic metabolites, it is generally held that metabolism of a drug to a reactive intermediate is a potentially deleterious property. In the drug discovery process, it has become commonplace to test new compounds for their potential to generate reactive electrophiles, using a variety of assay types [e.g., glutathione (GSH)-trapping assays, high throughput mutagenesis assays, and covalent binding assays]. Such data can be used as a mere screen, with an attempt to remove this property by blindly testing enough compounds so as to find one that lacks the property. However, the elucidation of the structure of nucleophile adducts as well as other metabolites downstream from a reactive intermediate is a more rational approach to solving such an issue. By identifying the substituent undergoing adduction with a nucleophile, such as GSH, advice can be provided to the medicinal chemist as to where the bioactivation is occurring and how it can be abated with structural modifications.

5.1.1.4 Identification of Pharmacologically Active Metabolites. When a drug undergoes metabolism, there is no *a priori* reason to assume that the metabolite will not possess a similar pharmacologic activity profile. In fact, there are numerous drugs known to possess metabolites that also contribute to the desired pharmacological effect (e.g., fluoxetine, loratadine, and atorvastatin). Thus, the identification of metabolites with pharmacological activity is important for two reasons. (i) To understand the relationship between the pharmacokinetics and pharmacodynamics, the concentrations, plasma protein binding, and target tissue penetrability of not only the parent drug but also all active metabolites must be known. This permits the setting of appropriate dosing regimens. (ii) To protect the intellectual property rights of an inventor of a novel drug, knowledge of metabolites that contribute to activity must also be known; otherwise, others could investigate this and claim the metabolites as potential new drugs in their own patents.

A first clue to the existence of active metabolites *in vivo* can be discerned from disparities between the potency of the parent drug measured *in vitro* and the concentrations *in vivo* associated with activity. Also, if the pharmacological effect is prolonged relative to the pharmacokinetics of the parent drug, it is possible that a long-lived active metabolite could be responsible. Of course, these observations could be due to other factors, such as inherent properties of the systems biology underlying the pharmacological target, but if observed, an investigation of the possibility of active metabolites is warranted. The other means by which active metabolites are identified is via a simultaneous examination of the structures of metabolites and the known structure-activity relationship (SAR) of the series. If small modifications (e.g., *N*-demethylations and hydroxylations) are introduced by metabolism at portions of the chemical scaffold known to be areas where the target receptor SAR is relatively loose, the possibility that the metabolite possesses pharmacological activity is heightened. It should be appreciated that there are even rare cases where a metabolite possessing substantial alterations in structure relative to the parent can possess target receptor potency (e.g., morphine glucuronide).

From these four aspects, it is apparent that metabolite structure elucidation can play an important role in drug discovery activities, aiding in drug design to optimize pharmacokinetics and reduce the likelihood of toxicity, as well as providing a clear understanding of the pharmacology of the target.

5.1.2 Metabolite Structure Elucidation in Drug Development

The characterization of the metabolic profile of a new drug is well recognized as an essential and required element in the introduction of a new drug to clinical use. This has been a mainstay of ADME/PK groups in the pharmaceutical R&D industry for decades. Unlike the targeted metabolite structure elucidation activities used in support of problem solving in drug discovery, the structure elucidation activities in drug development tend to be similar from compound to compound as they are done to provide a comprehensive, quantitative, and thorough picture of the total metabolism of a new compound. In drug development, metabolite structure elucidation is done for the following two main purposes:

1. To provide a comparison of metabolites in human to those in the laboratory animal species used to assess the safety and

2. To provide a complete picture of the total disposition of the drug in human to enable gathering needed knowledge of the main clearance pathways and the enzymes involved.

5.1.2.1 Cross-Species Comparison of Metabolite Profile. In the development of new drugs, thorough testing of safety is carried out using laboratory animal species. Testing for general target organ toxicity, reproductive toxicity/teratogenicity, genetic toxicity, carcinogenicity, and safety pharmacology is done using various animal species for each test (mostly mouse, rat, rabbit, dog, and monkey). When these safety studies are done, the parent molecule is being tested and metabolites are also being tested by virtue of their being generated *in situ*. Thus, the determination of the structures and abundances of metabolites in humans and a comparison of these to that in laboratory animals is important in determining whether the animal species were exposed to the metabolites present in humans. If there are metabolites present in humans and no animal species generated these metabolites, then the extrapolation of conclusions made from animal safety tests to the human situation would not necessarily be as valid. The same would be true for metabolites unique to an animal species, since it would be possible that the toxicity observed in that species could be due to the metabolite and not anything to which humans are exposed. Granted, it is highly unlikely that any given drug will yield a profile of metabolites identical in structure and prevalence across humans and animal species. Nevertheless, there is a reasonable expectation that these profiles will be similar and that the exposure to any given metabolite will be greater in at least one of the animal species as compared to humans, largely due to the fact that doses (per body weight) given to animals in toxicology studies are considerably greater than those given to humans in clinical trials.

For these reasons, a comprehensive comparison of metabolites across species is important and is an essential element to the data set describing the properties of a new drug to physicians and government regulatory agencies.

5.1.2.2 Determination of Human Clearance Pathways. Knowledge of how a drug is cleared from the body is important because this can be a major factor in defining the interpatient variability of pharmacokinetics. Drug-metabolizing enzymes and transporters are expressed at different levels in different people. This can be due to inherent factors (e.g., genetics, age, and disease) or environmental factors (e.g., drug interactions and diet). The clinical pharmacology literature is rife with examples of investigations of the determinants of interpatient variability in pharmacokinetics. Genetic polymorphisms of important drug-metabolizing enzymes, such as CYP2D6, CYP2C19, CYP2C9, FMO3, UGT1A1, and others, have been described, in some cases, with prevalence of genotypes linked to geographical or ethnic origins, and their impact on drug pharmacokinetics well established. Drug–drug interactions with all the major cytochrome P450 enzymes have been described, with some at greater frequency (e.g., CYP3A) than others.

The identification of the total metabolic pathways of a new drug provides the first critical foundation on which the knowledge of mechanisms of interpatient variability can be built. An examination of the profile of metabolites in urine and feces of human after administration of a dose containing a radioactive atom in the molecule (typically carbon-14) allows the entire dose to be accounted for. The metabolites are identified such that the pathways can be logically constructed from the types of reactions that

have occurred to generate each metabolite. Then the fraction that each metabolite contributes to the whole dose can be calculated from the quantitation done using the radioactivity. This information is combined with the metabolic pathway scheme, and the percentages that each of the initial pathways from the parent drug contributes to its clearance can be calculated. From this knowledge, appropriate *in vitro* studies can be designed to elucidate the enzyme(s) involved in each initial pathway. When that information is obtained, it can be used to inform clinical pharmacologists of the types of investigations needed to determine the reasons behind interpatient variability, which types of drug–drug interaction studies should be done, whether drug pharmacokinetics in renally or hepatically impaired patients should be studied, and so on. Thus, while the studies needed to define interpatient variability extend far beyond the identification of metabolites, the latter is a fundamental first step in this process.

5.2 SAMPLE GENERATION AND WORKUP

Before any structure elucidation work can be accomplished using modern spectroscopic methods, an appropriate sample workup procedure needs to be applied. In the past, the procedures needed could be rather arduous because the main spectroscopic tool used was gas chromatography-mass spectrometry (GC-MS), which required considerable cleanup of samples and derivatization reactions. With the advent of HPLC-MS in the 1980s and 1990s, sample workup has become considerably simpler. Nevertheless, there are still some procedures required for many of the types of samples in which metabolites need to be identified. Fundamental elements of any sample workup procedure are as follows:

1. The procedure needs to be “comprehensive”—metabolites must be recovered through the procedure with efficiencies equivalent to each other.
2. The procedure must be gentle enough so as to not chemically modify metabolites.
3. The procedure must strike a balance between maximizing metabolite recovery while adequately removing endogenous interferences from the sample matrix.
4. The procedure must result in a mixture that can be analyzed by chromatography and spectroscopy (e.g., for standard reversed-phase HPLC, the sample must be miscible with aqueous solvents, not too viscous, and devoid of particulates that can clog an injector).

5.2.1 *In Vitro* Samples

The generation of *in vitro* samples for metabolite identification has become a very important procedure for gaining an understanding of metabolite profiles in drug research. It offers the advantages of permitting the use of human-derived reagents before clinical research to gain a prediction of human metabolite profile as well as reductions in the use of animals in research and the associated costs. *In vitro* metabolite profiles generated with human-derived reagents (e.g., hepatocytes, liver subcellular fractions, and expressed human drug-metabolizing enzymes) can fairly reliably identify the main clearance pathways of a new drug, albeit they are not perfect in generating a complete match to the *in vivo* metabolite profile [1]. Nevertheless, *in vitro* metabolite profiles are very valuable in addressing the challenges in drug discovery described in Section 5.1.1.

Selection of the best *in vitro* system for the task at hand is critical in order to generate a metabolite profile most appropriate to the *in vivo* situation. This is largely based on the substituents present in the molecule (i.e., what types of common drug metabolism reactions could occur and which enzymes would catalyze these reactions) and the question being addressed (i.e., main initial clearance pathways or a comprehensive total metabolite profile). If the structure of the molecule is such that only oxidative types of reactions could occur, the use of liver microsomes supplemented with NADPH may be all that is needed to ensure the activity of the cytochrome P450 enzymes. If substituents are present on the molecule that can undergo conjugative metabolism, a more complete *in vitro* system such as human hepatocytes or liver S-9 fraction supplemented with multiple cofactors needed by the various drug-metabolizing enzymes (e.g., uridine diphosphoglucuronic acid (UDPGA), S-adenosyl methionine (SAM), Adenosine 5'-phosphosulfate 3'-phosphate (PAPS), and acetyl coenzyme A) will be needed. And if the possible generation of a reactive metabolite is being investigated, inclusion of GSH in the *in vitro* system will also be important. The concentration of the substrate is also important as a balance must be achieved between using those concentrations predicted to be relevant to *in vivo* and those offering adequate quantities of metabolites for spectroscopic characterization. Since the compound will have different enzyme kinetics with the various drug-metabolizing enzymes, different metabolite profiles will be obtained with different substrate concentrations. A concentration between 1 and 20 μM is typically high enough to provide robust spectroscopic data while not being so high as to generate an unrealistic metabolite profile. Lower concentrations can be accommodated if the *in vitro* incubation volume is relatively high ($>2\text{ mL}$). Incubation times can vary, depending on the enzymes involved and the lability of the substrate. Liver microsomal incubations for P450 enzymes are usually run for 10–60 min, whereas for suspended hepatocyte incubations for 0.25–4 h.

Relative to *in vivo* samples, *in vitro* samples are “clean” of endogenous materials, and thus relatively simple sample workup procedures can be applied. In almost all cases, a simple procedure in which the incubation is terminated by addition of a miscible organic solvent such as acetonitrile or methanol is applied. This serves to precipitate the proteins while still maintaining the drug-related materials in solution. The precipitated protein can be removed by spinning the sample in a centrifuge. If enough solvent is added, buffers and salts present in the incubation will also be precipitated. The solvent chosen should be one that is miscible with water and that has relatively low boiling point for ease of evaporation. In most cases, acetonitrile is preferred since it is aprotic, while alcohols can react with some metabolites (e.g., form esters with carboxylic acid metabolites) to form metabonates.

After the precipitated proteins and salts are spun down, the supernatant is transferred to a new tube for evaporation of the remaining mixture of solvent and water. This is done for two reasons: to concentrate the sample for maximization of the response in the subsequent spectroscopic analysis and to ensure that excessive solvent will not confound the chromatography. Evaporation can be accomplished in several manners, but it is important to not apply excessive heating of the sample in the case that the metabolites are temperature sensitive. Commonly used practices include evaporation under a stream of inert gas such as nitrogen, evaporation under vacuum (e.g., vacuum centrifugation), and lyophilization. The latter is the most gentle process but takes the longest. Vacuum centrifugation offers the advantage that the sample will be concentrated into a small surface at the bottom of the tube, whereas evaporation under flowing gas will

tend to spread the sample out over a larger surface in the tube. (This can be important for effective reconstitution of the sample.) The evaporated sample is reconstituted in a small volume of mobile phase used for HPLC-MS analysis. To aid in reconstitution, the residue can be subjected to vigorous mixing on a vortex mixer and/or sonication. Depending on the amount of *in vitro* reagent used, there may be some cloudiness (due to lipids) or particulates in the reconstitution mixture; these should be removed by centrifugation before injection on HPLC or one runs the risk of clogging the injector and/or column.

5.2.2 *In Vivo* Samples

The analysis of *in vivo* samples for metabolite profiles is considerably more challenging than *in vitro* samples. This is due to the large number of endogenous interferences present, the generally lower concentration of drug-related materials, and for fecal and tissue samples, the need to homogenize the samples before extraction. For *in vitro* investigations of drug metabolism, the drug metabolism scientist has more control over “engineering” the sample to meet the need. However, for *in vivo* drug metabolism investigation, the nature and quality of the samples obtained is dictated by how the body handles the drug and the limitations on the dose that can be administered. For example, when analyzing plasma samples for metabolite profile, the concentrations can be so low as to prohibit gathering rich spectral data, and these low concentrations can be due to either a low dose administered or a proclivity of drug-related materials to readily distribute into tissues, or both. These types of phenomena create challenges for scientists engaged in the identification of metabolites *in vivo* and drive aspects of the sample workup procedures employed.

5.2.2.1 Urine and Bile Samples. Among the *in vivo* samples that are typically analyzed for metabolite profiles, urine and bile samples generally have the simplest sample workup procedures. These are excretory fluids, and thus the body excretes foreign materials such as drugs and their metabolites into these fluids, thereby concentrating them. In particular, for small animals (rats and mice), the concentrations of drug metabolites in urine and bile are generally high enough that no concentration step is needed, and the samples can be directly injected onto HPLC-MS without any sample workup beyond simply removing particulates by centrifugation and adjusting the pH of the sample to match that of the HPLC mobile phase. Such a simple procedure assures that there are no selective losses of individual metabolites. However, because of the large amounts of endogenous materials, it yields the challenge of sifting through HPLC-MS chromatograms to distinguish drug-related entities from endogenous compounds. It is thus critically important to compare the data to control samples. The best control samples are collected from the same animals/humans before administration of the drug, since the identities and quantities of some endogenous interfering materials will be specific to the individual and the environmental conditions of the study site (e.g., diet components and collection vessels). For larger species, the concentrations of drug-related material in urine and bile will be lower and may require a concentration step, such as lyophilization, vacuum centrifugation, or evaporation under nitrogen. Of course, in addition to the drug-related materials of interest, the endogenous interferences will also become more concentrated.

Urine and bile samples can also be subjected to solid-phase or liquid extraction techniques. The risk of these is that recoveries of the different metabolites may begin to differ and thus yield a metabolite profile that has been altered. For liquid extraction, water soluble and very polar metabolites such as the glucuronide, sulfate, or GSH conjugates are not extractable from aqueous solutions. When using samples from a radiolabel study, total recovery through the process can be readily assessed with liquid scintillation counting, and if recoveries are >90%, it is reasonable to assume that recoveries of drug-related materials through the process are equal. Selection of a solid-phase sorbent can be done such that the principles used to retain and elute the drug-related material can be orthogonal to the principles used in the chromatography of the HPLC-MS method. For example, if the HPLC-MS analysis is done using a reversed-phase C18 column, then the solid-phase extraction (SPE) can use an ion exchange resin. For liquid extraction, recoveries for some polar metabolites can suffer. Adjustments of pH can be employed to enhance recoveries, but extremes of pH (e.g., <2 or >12) should be avoided because some metabolites may degrade. Commonly used liquid extraction solvents include methyl tertiary butyl ether (MTBE), ethyl acetate, chloroform, dichloromethane, or polar solvents such as *t*-butyl alcohol or a mixture of isopropyl alcohol and toluene. Isopropyl chloride is another solvent that can be considered for extraction of drug components. Although not often used, this can be an excellent solvent for extraction purposes considering its properties (boiling point 36°C, dielectric constant 9.82, and water solubility 1.3%).

Bile samples have the added complexity of possessing high concentrations of bile salts. These can act in a detergentlike manner to alter the chromatography and cause small shifts in retention times of metabolites. They can also elute on reversed-phase HPLC columns at retention times of interest, when metabolites elute, and suppress the ionization of the metabolites. When analyzing the metabolite profile in bile samples, one must be aware of this possibility and limit the volume of bile injected as much as possible.

5.2.2.2 Fecal Samples. Fecal samples offer unique challenges in profiling metabolites because unlike urine and bile, they are not homogeneous liquids. Thus, they must be adequately diluted (with water or a water-miscible solvent) to permit homogenization as well as an ability to pipette discrete volumes. Sample consistency can vary considerably across species, individuals, and with diet; thus, there is no single best method of handling such samples and the investigator must qualitatively assess the process in real time in each instance. When analyzing fecal samples from a radiolabel study (which is almost always the case for this matrix), recovery through the homogenization and extraction process can be measured. Typically, solid samples are homogenized with water, at 2–4× the weight, using a stomacher mixer or probe homogenizer. This yields a slurry that can be used for subsequent extractions. The key to success is to physically remove the drug-related material away from the particulate matter. The slurry can be spun in a centrifuge, the supernatant removed, the particulates resuspended in solvent (water or a mixture of water and miscible solvent), followed by vigorous mixing to extract drug-related materials. Mixing can be done using a vortex mixer, shaking mixer, or sonicator, and the use of sequential combinations of these techniques with relatively long times (e.g., hours) can increase yields. Once a good recovery (>85%) is obtained in a liquid phase combined from the series of extractions, it is evaporated as described above. In general, the solid residue obtained from fecal extracts can be difficult to

work with, depending on the quantity extracted and the techniques used. Reconstitution into HPLC mobile phase may also require physically vigorous conditions such as sonication. As with other samples, a final removal of particulates from reconstituted samples should be done to avoid clogging the HPLC.

5.2.2.3 Plasma and Tissue Samples. The analysis of plasma samples for metabolite profile generally offers the challenge of low concentrations of metabolites relative to excreta samples. Thus, sample workup of plasma has two aims—to remove endogenous materials, especially protein, and to concentrate the sample. For example, to generate high enough amounts of metabolites from plasma to get rich spectral data, it is not uncommon to need to workup samples in excess of 1 mL for a single injection.

Workup techniques for plasma almost always involve a deproteination step. This is frequently done with addition of water-miscible organic solvents (such as 3–5× volumes of acetonitrile). Alternately, deproteination can be done by lowering the pH with trichloroacetic or trifluoroacetic acid, although one must be careful that potential metabolites are not acid labile. The proteins are removed by spinning in a centrifuge, and the supernatant is evaporated either by lyophilization, under vacuum, or under flowing nitrogen gas. The residue is reconstituted in HPLC mobile phase, and particulates are removed by centrifugation before injection on HPLC. In some cases, depending on the amount of plasma analyzed, there can be lipids present in the reconstituted mixture. These can be removed by centrifugation, although completely removing them can be challenging because they will float at the top of the supernatant. As with urine and bile samples, plasma samples can be analyzed by SPE or liquid extraction to yield samples with fewer endogenous interfering materials, albeit with the same caveats regarding recovery of analytes. Use of radiolabel can permit recovery to be tracked through such procedures. When using SPE of plasma samples, interactions between metabolites and plasma proteins (e.g., albumin and acid glycoprotein) must be disrupted before application to the extraction cartridge. Otherwise, the analytes may preferentially associate with the plasma proteins over the solid-phase matrix and be carried through the cartridge when the sample is applied.

To address some questions, it may be necessary to assess metabolite profiles in specific tissues. Tissue samples are best treated like plasma samples, with the added complexity that a homogenate must first be made to provide a liquid for processing. If the tissue is one possessing a high capability to metabolize drugs, such as liver, precautions will be needed to assure that further metabolism does not occur during homogenization, such as keeping the sample cold until protein is removed. Some tissues, such as brain and adipose, will possess a high amount of lipid such that the homogenates may need a prewash with hexane or petroleum ether to help remove excess lipids before further processing.

5.3 HPLC-MS ANALYSIS

Metabolite identification and profiling consist of three essential steps, namely separation, detection, and structural analysis of metabolites. With the advances made in each of these categories, the identification of drug-related components has become routine in a drug development setting and can even be accomplished rapidly enough in a drug discovery setting to help influence chemical design.

5.3.1 Chromatographic Separation

Chromatographic separation of metabolites from endogenous components has a vital role to play in metabolite identification. For identification of all metabolites, it is important that the separation be of high resolution and in high capacity. Several chromatographic tools have been used to accomplish this, and all operate under a common principle that compounds in a mixture interact differently with the stationary and mobile phases employed by a specific chromatographic method. Currently, the most commonly used chromatographic technique is HPLC. Some techniques less frequently employed include GC and thin layer chromatography (TLC). Other more sophisticated methods of separating drug-related components have also been tried (albeit sparsely), including supercritical fluid chromatography (SFC) and capillary zone electrophoresis. Although the separation of metabolites in older metabolite identification studies was conducted using TLC [2], it was quickly superseded by other separation methods that offered both high accuracy and sensitivity for the analysis of highly complex mixtures of compounds. GC was one such method that used inert carrier gases such as nitrogen and helium as the mobile phase and was highly efficient and sensitive in resolving the constituents in a mixture that were volatile enough to be vaporized [3–5]. Most drugs and their metabolites are nonvolatile and required derivatization before analysis, and several derivatization techniques have been reported. Several examples of use of GC in drug metabolism studies have been reported. One application of GC in drug metabolism studies is its use in determining which enantiomers are formed when the metabolic process produces a chiral center in the metabolite. For instance, the use of GC has been demonstrated in determining the abundance of the reduced metabolite of diethylpropion. Reduction of the carbonyl group in diethylpropion to an alcohol introduces a chiral center in the molecule, resulting in the formation of two enantiomers. The amount of the reduced metabolites was determined by derivatizing the alcoholic group with *N*-trifluoroacetyl-*L*-propyl chloride, and the diastereomers obtained were analyzed by GC [6]. Despite its high efficiency, GC suffers several disadvantages that have made the process of identifying metabolites cumbersome. First, the compounds have to be volatile enough to vaporize for analysis and detection. Alternatively, the analytes have to be derivatized before analysis. This results in increase in analysis time, which is not amenable to the high throughput that is required in discovery. Second, the compounds/analytes should be stable at high temperatures. Last, the highly soluble phase II conjugates of the drug are difficult to analyze by GC and cannot be detected intact. Most often, these require enzymatic digestion before analysis. Thus, GC has generally fallen out of favor among scientists engaged in metabolite structure elucidation; however, there are some instances where its use is advantageous.

In the past few decades, HPLC has replaced the use of GC methods in the conduct of drug metabolism studies [7,8]. The need for analytical methods with increased sensitivity, stability, and speed to separate these polar components has made HPLC a routine method for drug metabolism studies. The three particular advantages of HPLC over GC are (i) water-soluble compounds can be analyzed without extraction and derivatization, (ii) all analysis can be performed at room temperature, and (iii) it is nondestructive. In drug metabolism studies, the use of HPLC is dictated primarily by the fact that metabolites are typically more polar than the parent drug (and thus more water soluble). In HPLC, the separation of various components of the mixture depends on their distribution between the stationary and liquid mobile phase and the relative

affinities for the two phases. The instrumental and theoretical aspects of HPLC are well documented and are not discussed further.

Advances in this separation technology have greatly enhanced the capabilities of liquid chromatography (LC) in separating complex mixtures, not only in terms of resolution and associated speed of separations but also with regard to the capacity and robustness afforded by the current generation of columns, autosamplers, pumping systems, and so forth. Traditional 2.1- and 4.6-mm reversed-phase columns have filled this need for some time and their use in HPLC is a mature technique. However, there have been significant advances in column technology, including decreased particle size, increased porosity, chemical stability, and bonded ligands. In recent years, development and commercial availability of porous stationary phases with particle sizes $<2\ \mu\text{m}$ has enabled better separation with increased sensitivity and faster resolution. Although the default technique for metabolite identification is reversed-phase chromatography, related techniques such as hydrophilic interaction chromatography (HILIC), which use low aqueous/high organic mobile phase, is emerging as a valuable supplement to the reversed phase HPLC and might offer advantages for the retention of very polar metabolites [9,10]. HILIC is based on the hydrophilic interactions between ionic analytes and zwitterionic groups covalently bonded to silica or polymer beads, for example, $-\text{CH}_2\text{N}^+(\text{CH}_3)_2\text{CH}_2\text{CH}_2\text{CH}_2\text{SO}_3^-$, which provides a separation mechanism orthogonal to that of reversed-phase HPLC. This technology separates compounds by eluting with a strong organic mobile phase against a hydrophilic stationary phase where elution is driven by increasing the water content in the mobile phase. The highly volatile organic mobile phases such as methanol and acetonitrile used in HILIC provide an increased ionization efficiency for MS/MS detection (discussed later) and low column backpressure to perform fast chromatography. Other approaches such as the monolithic and microcolumn technologies have also seen increasing use in achieving chromatographic separation of metabolites. Monolithic columns are advantageous because of their high permeability, which allows the use of higher flow rates and therefore shorter chromatographic runs. High porosity of these columns render less backpressure than conventional columns at similar flow rates and which make higher speed separation possible without disruption of chromatographic resolution [11,12]. Microcolumn technique on the other hand adopts a shorter ($<5\ \text{cm}$ length) narrow-bore ($\sim 2\ \text{mm}$ i.d.) column packed with small particles and operated at higher-than-optimal flow rates to provide for fast chromatographic separations while still maintaining satisfactory chromatographic resolution. The reduced inner diameter of these columns is advantageous in the metabolite identification field because of its capability to use limited sample amount compared to conventional columns [13,14]. The most recent developments deal with the use of separation on a chip, which may be easily coupled with nanoelectrospray ionization with extremely low sample and solvent consumption and enormous sensitivity [15].

The latest chromatographic technique is ultraperformance liquid chromatography (UPLC), which is based on the same working principle as HPLC while utilizing smaller particles ($\sim 1.7\ \mu\text{m}$) as stationary phase and is able to perform under much higher liquid pressures (up to 15,000 psi). This technique allows the liquid handling system to handle the high backpressure resulting from the stationary phase with $<2\ \mu\text{m}$ particles. UPLC has generated considerable interest in many areas of research and has been applied to metabolite identification for a variety of sample types [16–18]. The increased chromatographic resolution of the technique, achieved via reduced particle size packing materials and high pressure LC systems, has resulted in dramatic

improvements in chromatographic resolution. This offers significant advantages for metabolite characterization and has led to the technique being commonly coupled to MS, where the rapid scanning speed allows the acquisition of sufficient data points across very narrow peaks [19,20].

The modifications caused by metabolic reactions can have major effects on the chromatographic behavior of metabolites. In most cases, the metabolic changes lead to an increased polarity of the metabolites and therefore decreased retention in reversed-phase HPLC systems in relation to the parent drug. The polarity increase and simultaneous retention decrease is particularly relevant for high polar metabolites, such as sulfates, glucuronides, and other polar conjugates. The separation of the parent drug and polar metabolites in one chromatographic run usually requires the use of gradient elution and often the addition of ionic modifiers into the mobile phase to increase the retention of polar conjugates. The type of mobile phase used in the separation depends on the detector that is used in the identifying the metabolites. Common HPLC methods for the analysis of drugs and their metabolites frequently rely on the use of nonvolatile buffers and additives, such as phosphate buffers and other inorganic additives. Since the use of an MS detector for identifying metabolites has become the common practice (see below), nonvolatile buffers have been replaced by mobile phases containing volatile modifiers. Organic acids such as formic or acetic acid (0.1% concentration) or their ammonium salts (2–10 mM) are typically used as aqueous solvents when performing LC-MS experiments [21,22]. Although trifluoroacetic acid is a favorite ionic additive in HPLC assays for biological compounds such as peptides, it may cause serious ion suppression effects in HPLC-MS [23,24]. For an alkaline environment, ammonium hydroxide in a similar concentration range has been used with HPLC columns with an extended stability at alkaline pH [25]. If ion-pairing HPLC is needed for the successful separation, dialkylammonium or trialkylammonium acetates or formates are recommended for negatively charged analytes and perfluorated carboxylic acids for positively charged analytes [21,26].

5.3.2 Detection

Generally, the chromatographic separation techniques are coupled with appropriate detectors by which the separated drug-related components can be readily detected. Some common detectors used are ultraviolet–visible (UV–vis), fluorescence, or electrochemical detectors. However, in case a radiolabel analyte is available, radioactivity detectors including radioflow detection, microplate scintillation counting, stop-flow/dynamic flow radioflow detection, and microplate radioactivity imaging techniques are often used for detection purposes. In the past two decades, MS and NMR (discussed later in the chapter) have emerged as ideal detectors for identifying structurally diverse metabolites in the incubation mixtures or biological samples obtained from animals or humans.

Both UV–vis as well as fluorescence spectroscopy find widespread use in the early stages of metabolic studies. However, the UV–vis detectors are more commonly used in early drug discovery setting, when radiolabeled materials are generally not available. These techniques are sensitive and informative enough to be applied to a range of metabolic problems. Both fixed (254 nm) or variable wavelength detectors as well as photodiode array (PDA) detectors have been used in line with HPLC or UPLC separation systems. Since many metabolic transformations do not generally alter the

UV chromophore of the drug to a great degree, the UV chromatogram allows detection of most drug-related peaks that are present in the biological sample, and a crude comparison of abundances among the metabolites can be made. However, sometimes, a metabolic transformation of a compound (e.g., aromatic oxidation) can modify the UV chromophore and as a consequence, the relative quantitative importance of a metabolite may be over- or underestimated. The PDA detectors can sometimes overcome this problem since array detectors are especially useful for recording the full UV–vis absorption spectra of samples that are rapidly passing through a sample flow cell. This characteristic of the diode array detectors makes it particularly useful in drug metabolism studies and for identification of unknown compounds. A general strategy used is to compare the UV chromatogram of the biological sample containing the drug-related material with that of the control (devoid of the drug or drug-related material). This allows one to distinguish the drug-related material from the endogenous peaks in the biological sample. While UV–vis can be extremely valuable for samples from *in vitro* incubations, its application to *in vivo* samples can be compromised by the vast array of endogenous chemical entities that will also have UV–vis absorbance. Most software allows subtraction of the UV chromatogram obtained from the control sample and hence allows the detection of most drug-related peaks in the mixture. The successful application of UV–vis is highly dependent on the absorbance characteristics of the compound of interest. If substantial absorbance occurs at wavelengths of 250 nm or greater, the UV–vis chromatogram will be of use (provided that the concentrations of test compound and metabolites are not too low). However, the amount of structural information that can be derived from a UV or a fluorescence spectrum is not sufficient enough to characterize the structure of the metabolite solely by these means. The best use of UV in identification is when these detectors are used in conjunction with mass analyzers and are placed between the chromatographic separating system and the mass spectrometer. The current practice in the pharmaceutical industries is to place a PDA detector between the HPLC and MS.

5.3.3 Mass Spectrometry

5.3.3.1 Instrumentation and Scanning Techniques. In the past 20 or more years, MS has emerged as a standard technique for identification and characterization of metabolites in incubation mixtures or biological samples. It can be easily coupled with both gas- and liquid-phase separation techniques in the analysis of complex biological samples; it has an extremely high sensitivity and low sample consumption, and the required information may be obtained relatively easily by a proper selection of ionization technique and mass analyzer. The advantage of MS resides in its ability of being able to not only serve as a detector but also provide structural information for the compound of interest. This information provided by MS detectors comprises a molecular ion of a compound and a mass spectrum that provides fragment ions specific to a molecule. As a result, this technique has revolutionized the process of metabolite identification. Hyphenated techniques in which a chemical separation technique such as GC, HPLC, or SFC is interfaced with an MS system have become standard practice in drug metabolism studies. Owing to their inherent sensitivity and selectivity, these hyphenated systems normally do not require labor-intensive sample preparation procedures or prolonged chromatographic run times. Further, the technique is extremely robust and rapid and can be readily automated.

The first popular hyphenated technique to be used for drug metabolism studies was GC-MS [27–29]. In this system, the highly efficient capillary GC was coupled to MS analyzer that employed electron impact (EI) or chemical ionization (CI) as a mode of ionization. Because the output from the GC column is in the vaporized form, it was readily amenable to MS analysis. Further, the MS analyzer was able to produce structural information within the peak width obtained from GC separation. Hence, this combination was the best mode for identifying and getting structural information of drug-related components. However, as described previously, the application of GC-MS is limited to volatile, nonpolar, easily extractable organic compounds and highly volatile compounds with low vapor pressure [30]. Since most drug metabolites are more polar than the drug from which they are derived, they can have considerably less volatility. Thus, the detection of these metabolites from biological samples requires analyte extraction into an organic solvent before analysis frequently followed by chemical derivatization of the analytes [31,32]. Although this is feasible, the extra work-up required for this analysis not only reduces the speed in metabolite identification but also does not give proper structural information, especially of phase II metabolites. Further, some metabolites are prone to undergo “on-column degradation” because of the high temperatures that are employed in the GC methods. Despite these limitations, GC-MS remains a useful analytical tool for metabolic profiling in various biofluids, such as urine and blood, due to its high sensitivity, peak resolution, and reproducibility [5]. Many GC-MS approaches to metabolite structure elucidation rely on derivatization with a silylation reagent before analysis to convert the polar functional groups that are problematic in GC-MS analysis to less polar groups. In addition to one-dimensional GC-MS techniques, methods in which a comprehensive two-dimensional GC coupled with a time-of-flight (TOF) mass spectrometer are used to identify a broad range of small, moderately polar to polar metabolites. Recently, an analytical method using in-line silylation coupled to GC-MS, which is suitable for metabolic profiling in ultrasmall sample volumes of 2 μ L down to 10 nL, has been reported [33].

The need to detect polar compounds in aqueous media directly without the limitations imposed by derivatization and/or extraction for GC-MS analysis led to the interfacing of HPLC with MS. HPLC-tandem mass spectrometry (LC-MS/MS), in which the HPLC system and the tandem mass spectrometers (MS/MS) are in line, is by far the most used technique for structural characterization of metabolites and a cornerstone in metabolite identification in the past 20 years. Two types of tandem mass spectrometers are used in the biotransformation studies. These are the triple quadrupole tandem mass spectrometer [34] and the 3D and linear ion traps [35,36]. Like the GC-MS, the LC-MS/MS technique is highly sensitive in detecting drug-related material in biological samples. Its ability to separate, detect, and identify many diverse metabolites with limited workup, especially in the presence of endogenous material, makes it a technique of choice for drug metabolism studies. The first generation of robust triple quadrupole LC-MS/MS systems became commercially available only in the early 1990s with the introduction of the Sciex API 3 mass spectrometer. Since then, advances in MS technologies have led to new mass analyzers such as the hybrid triple quadrupole–linear ion-trap (Q-trap) [37]. Further, commercialization of high resolution mass spectrometers, such as the TOF and quadrupole time of flight (QTOF) and the advent of Fourier-transform mass spectrometers (FTMS) or linear trap quadrupole orbitrap (LTQ-Orbitrap), have further improved the efficiency of metabolite profiling in pharmaceutical research. The latter instruments have added accurate mass capabilities

Figure 5.1 Scheme describing the product ion (PI) scan, precursor ion scan (PIS), and (CNLS) [44].

and help in providing accurate mass data for all ions in the spectrum, resulting in elemental composition information that is immensely valuable in the structure elucidation of drug metabolites in complex mixtures of biological origin [9,27,38–41].

Tandem mass spectrometers use two stages of mass analysis, the first to preselect an ion and the second to analyze the product ions (PIs) produced most commonly by collision activation with an inert gas such as argon, helium, or nitrogen. In addition to the full scan mass spectra that allow assignment of molecular weight, triple quadrupole mass spectrometers offer three scanning functions that can be used to detect metabolites and assign structures to them. The three scanning functions include PI scan, precursor ion scan (PIS), and constant neutral loss scan (CNLS) [42–44]. The schematics of the three modes of scanning are depicted in Fig. 5.1. In PI scanning mode, an ion of a given m/z value is selected in the first quadrupole, fragmented in the collision chamber that is positioned between the first and the third quadrupole, and the resulting mass-to-charge ratios of the fragment ions are analyzed in the third quadrupole. The spectrum thus obtained can be used to provide structural information for the compound or the metabolite. In PIS mode, the second mass analyzer is set to pass only the ions with a selected m/z value, while the first mass analyzer is scanned over a defined m/z range. In CNLS experiments, both the first and the third quadrupoles are operational in a way that the m/z difference between the mass spectrometers is kept constant, hence the term *constant neutral loss scan*. In both these scanning modes, the fragment ion or the neutral loss is generated in the collision cell.

Since the MS/MS scan modes are very specific in the ions that they are monitoring, the signal from the remaining endogenous material present in the sample is eliminated thus increasing the signal-to-noise ratio of a particular analyte. The PIS and CNLS modes of scanning have been very valuable in identifying conjugates of drugs in complex biomatrices. Thus, the triple quadrupole provides information that is more discriminatory for a particular compound and a data set that can be readily used for metabolite structure elucidation and biotransformation studies.

Ion-trap mass spectrometers have greatly influenced metabolite identification and its importance in early discovery. Because of the ease of use and the low cost, these mass spectrometers have become the “workhorses” to conduct biotransformation studies in early discovery. In addition to simplicity, the ion traps have improved sensitivity, specificity, and scan speed relative to TSQ mass spectrometers. The main advantage of the ion-trap mass spectrometer over the triple quadrupole mass spectrometers is its ability to collect sequential stages of ion fragmentation data (MS^n). Such fragmentation pathway data often simplify structure elucidation. However, unlike the TSQs, they are incapable of conducting experiments with PIS or CNLS. The LTQ is similar to the LCQ in terms of the experiments that can be performed; however, its capability to store more ions increases its sensitivity significantly over the conventional LCQs. A comparison of the triple quadrupole mass spectrometer and the ion traps has been described by King and Fernandez-Metzler [37]. An interesting aspect of this comparison is that the limitations of one instrument are the advantages of the other. In complex metabolite structure elucidation challenges, both types of instrument platforms can be leveraged in a complementary manner.

The high utility of the ion-trap mass spectrometers but the deficiency of these analyzers to conduct selective PIS and CNLS studies has led to further novel MS instruments that combine ion traps with TSQ, such as the MDS Sciex/Applied Biosystems 4000 Q trap [37]. The Q-trap mass spectrometers combine the functions of both triple quadrupole and linear ion-trap instruments and are capable of performing all the MS/MS experiments, including CNLS, PIS, multiple reaction monitoring (MRM), full scan MS-dependent MS/MS analysis, and the acquisition of MS^3 spectra. Additionally, these MS/MS experiments can initiate the so-called information-dependent acquisition of an enhanced product ion (EPI) spectrum, enabling detection of drug metabolites and acquisition of their PI spectra in a single LC-MS run. One of the unique scanning functions of the Q-trap is the EPI scanning mode. In this experiment, a metabolite ion is isolated in Q1, fragmented in Q2, and then, all fragments are trapped in Q3 with a subsequent trap scan. MS^2 spectra generated from EPI are similar to those recorded by triple quadrupole mass spectrometers in the PI scan mode.

The task of metabolite identification has been greatly facilitated by recent developments in high resolution LC-MS technology [e.g., Waters time of flight (QTOF, ThermoElectron Fourier transform (FT), and Orbitrap mass spectrometers]. As a result, a combination of high resolution MS and other types of LC-MS instruments has been recommended for metabolite identification. The hybrid QTOF accurate mass spectrometer has an additional quadrupole in front of a TOF analyzer, enabling the collision-induced dissociation (CID) of molecular ions [45,46]. This adds the ability of obtaining accurate mass PI spectra from the LC-MS/MS analysis and therefore allows the confirmation of molecular formula for proposed fragment ion structures [47]. This also simplifies the PI spectral interpretation for metabolite identification as demonstrated by Hop *et al.* [48]. When coupled with UPLC, it could significantly increase the analytical throughput and sensitivity for metabolite identification and profiling as a result of improved chromatographic resolution. Higher sensitivity lowers sample concentration requirements, whereas high resolution mass measurement ($\sim 5\text{--}10$ ppm) provides exact masses affording molecular formulae that are helpful for the identification of unknown metabolites. Even though the QTOF instruments can conduct fast data-dependent scanning for MS and MS^2 , they are unable to conduct MS^n experiments like the ion traps. Another limitation of the current LC/QTOF tandem instruments is

the inability to select the precursor ion with high resolution. The low resolution precursor ion selection may allow more than one species to be transferred to the collision cell where fragmentation occurs.

The more powerful hybrid LTQ-FTMS [49] and LTQ-Orbitrap mass spectrometer [50] combines the speed and sensitivity of the linear ion traps with the high resolution and accurate mass capabilities of a Fourier-transform ion cyclotron resonance (FTICR) mass spectrometer or the Orbitrap technologies [51]. These instruments are more sensitive than QTOF and provide mass accuracies better than 1 ppm with external mass calibration at resolutions as high as 100,000 for an acquisition rate of one scan per second. Both instruments have the potential to make metabolite identification as simple as a mathematical calculation based on accurate mass measurements and theoretical atomic weights of the elements known to compose the parent drug under study. LTQ-Orbitrap MS was introduced recently and is capable of high resolution full MS scan with improved signal-to-noise ratios. Like the ion traps, this analyzer can perform MSⁿ structural elucidation experiments. The practical limitation is the ability to rapidly store, retrieve, and process the large volumes of data the system can generate. The current version of LTQ-Orbitrap lacks ability of performing true neutral loss (NL), PI, and MRM scans that are available readily with a triple quadrupole or a triple Q-trap instruments. To overcome this type of drawback, several postacquisition data manipulation techniques, including mass defect filtering (MDF), background subtraction, neutral loss filtering (NLF), product ion filtering (PIF), and isotope pattern filtering (IPF), have been developed for mining data for metabolites.

5.3.3.2 Ionization. The most significant development to convert the aqueous HPLC effluent to gas phase was the advent and commercialization of atmospheric pressure ionization (API) techniques [52]. These techniques provide efficient ionization for various molecules, including polar, labile, and high molecular mass drugs and metabolites. In contrast to EI, which operates in vacuum and substantially fragments the analyte (i.e., rarely observe a molecular ion), the API interfaces operate at atmospheric pressure and cause very little fragmentation of the molecule. These ionization techniques are therefore referred to as *soft ionization techniques* and have become extremely popular in metabolite detection, identification, and quantitation because of their ability to couple easily to reversed- and normal-phase chromatography and generate intact molecular ions at very high sensitivity. Three different API sources are available. These are electrospray ionization (ESI) [53,54], atmospheric pressure chemical ionization (APCI) [55,56], and, the more recently introduced, atmospheric pressure photoionization (APPI) [57]. All three sources can ionize a variety of polar drug components in the aqueous media and can be operated in either a positive or negative ionization mode, which is governed by the voltage polarity of the capillary probe. The ESI technique is the most frequently chosen method in drug metabolism studies since it can be used to ionize compounds with a range of polarities and sizes. It is especially valued in the identification of metabolites since it enables the soft ionization of phase II metabolites, providing reliable information on the molecular weights of these conjugates without extensive fragmentation, unlike other ionization techniques. The mass spectra obtained from ESI fragmentation are relatively simple and yield intact analyte ion intensities. One characteristic of ESI is that the intensity of the ions is affected by the flow rate at which the matrix is introduced into the ion source. Higher sensitivity is generally achieved at lower flow rates. For instance, a flow rate in nanoliter per minute (the

nanospray technique) has resulted in even increased sensitivity compared to the conventional ESI where a flow rate of $\sim 50\text{--}500\ \mu\text{L}/\text{min}$ is introduced into the source. Despite the numerous benefits of ESI, this ionization technique is susceptible to ion suppression effects from high concentrations of buffer, salt, and other endogenous materials in matrix solutions.

The APCI source is a better ionization tool for the analysis of molecules that are nonpolar, relative to the ESI. This technique provides better ionization efficiency and sensitivity for these compounds. Although APCI also generates ions at atmospheric pressure like ESI, the ionization in APCI occurs mainly in the gas phase. This reduces the ion suppression and provides a wider dynamic detection range than ESI. A better tolerance to salts and matrix effects has been reported for APCI and APPI in comparison with ESI. Typically, a higher flow rate is used with APCI ($1\text{--}2\ \text{mL}/\text{min}$) than that in conventional ESI, and therefore this technique requires thermal desolvation. Because of this, extremely polar and large molecules ($\text{MW} > 1000\ \text{Da}$) are not well suited for APCI, where thermal degradation may reduce sensitivity. Both ESI and APCI can be used for small molecule ($\text{MW} < 600\ \text{Da}$) pharmaceuticals and drug metabolism studies. APPI also has a similar application range like APCI, but slightly extended toward nonpolar compounds. APPI has produced equal or better detection limits compared to APCI in selected applications; however, this technique still needs to be evaluated further before its broader implementation.

5.3.3.3 Strategies for Identification of Metabolites in Biological Matrices. As described previously, MS has evolved as an essential component of strategies used for fast metabolite identification. Several approaches using a variety of different mass analyzers have been described in the literature [27,40,41]. Regardless of the MS platform, drug metabolite identification by LC-MS techniques involves two steps: (i) detection of drug metabolite ions in a biological matrix and (ii) acquisition of their PI spectra for structural characterization. This can be supplemented by non-MS techniques, such as chemical derivatization, hydrogen/deuterium (H/D)-exchange, and NMR (see later), to provide specific structural information in cases where MS data alone are not sufficient to determine metabolite structure.

The most simple approach used in detecting and identifying metabolites in a biological matrix employs a full scan as a survey scan for searching for metabolites in the matrix [58,59]. This procedure involves analysis of test and control samples over the full mass range (typically scanning over a mass range that exceeds the m/z value for the parent drug by 400 mass units). After acquiring total ion chromatogram (TIC) data of the control samples (generally produced by a similar incubation lacking the study compound or *in vivo* matrix from an untreated subject) and study samples, the drug-related peaks are usually scouted by comparing the TIC of both these runs. When LC-MS is used in line with UV-vis (PDA) or radioactivity detectors, the detection of the peaks in the TIC is accomplished by matching the peaks and retention times in the UV or radiochromatogram with that in the TIC (Fig. 5.2).

The main advantage of this method is that all drug-related components that are present in the matrix can be detected and will generate an MS response as long as they are ionizable in the polarity that is used in the experiment. However, the method is only useful in detecting metabolites that are generated via known/expected biotransformation reactions such as hydroxylation and *N*-dealkylation and whose molecular masses can be readily predicted (predictable metabolites). Uncommon and novel metabolites

Figure 5.2 (a,b) Schematic of the arrangement of mass analyzers and UV or radioactivity detectors.

(unpredictable) that are formed via unconventional or multiple-step biotransformation reactions are difficult to detect using this method. Hence, when using this method, it is important to have a proper knowledge of all the biotransformation pathways. Further, the analysis can be confounded by the interfering ions from the endogenous material that are present in the biological sample.

The modification on the drug is generally determined by comparing the molecular ions of the peaks with those of the parent drug after background subtraction. The mass shift between the parent and the metabolite is the first indication of the type of biotransformation that the parent drug has undergone. The mass shifts occurring due to common metabolic pathways and predictable metabolites are shown in Table 5.1. Mass shifts of uncommon metabolites are generally difficult to predict from such a comparison with parent drugs. It is also worthwhile to apply the so-called nitrogen rule, which states that molecules of an odd MW possess an odd number of nitrogen atoms, while those with an even MW possess either an even number of nitrogen atoms or no nitrogen atoms. The formation of nitrogen-containing metabolites (e.g., amino acid conjugates or GSH adducts) or the loss of a portion of the molecule possessing a nitrogen will cause a characteristic change in the odd/even character of MWs. While this approach is likely to be reliable for common biotransformation pathways, more unusual metabolic reactions may sometimes be overlooked.

The most effective comparison of data acquired from the sample and the negative control is using software developed for this purpose. A number of software packages exist to enable targeted detection of potential drug-related components from complex data [60]. The information of the parent compound (molecular formula and some additional parameters restricting the screen) is fed into the software, and the chromatograms are screened automatically to show peaks present in the sample but absent in the negative control. These software packages have built-in intelligence to suggest identification of the detected metabolites. Extracted ion chromatograms for expected metabolites based on predicted molecular mass changes relative to the parent compound's molecular weight can therefore be constructed. Predictive software may improve the coverage of metabolite detection and can help expedite the detection

TABLE 5.1 Possible Metabolic Reactions and Related Changes in Mass of the Product [10,40,41,148,149]

process of common drug-related metabolites. However, the approach is not guaranteed to detect all the significant metabolites in biological samples and is not applicable to the detection of uncommon metabolites.

The structure of detected metabolites is generally elucidated in the following run in which the PI spectra (MS^2) of the molecular ions are acquired [10]. In cases where an ion trap is used, data-dependent scanning experiments are triggered, which enable the immediate generation of PI or MS^n data that can supplement PI scanning data via elucidation of additional fragmentation pathways. Therefore, both metabolite detection and MS/MS spectral acquisition can be accomplished in a single LC-MS run. The MS^2 and MS^3 spectrum obtained gives a fragmentation pattern that is characteristic of a metabolite. Interpretation of spectral patterns using basic interpretation rules allows one to propose a structure for the drug-related peak. For basic interpretation rules of the mass spectrum, reference to the specialized literature for electron ionization and soft ionization techniques is recommended. Although the fragmentation pattern can give

- Get a mass spectrum (CID spectrum) of the parent drug.
- Interpret the spectrum.
- Select specific product ions from the spectrum for precursor ion scanning experiment.
- Determine the specific neutral losses (CNL) in the fragmentation pattern to run a constant neutral loss scan experiment.
- Determine the mass spectra of the molecular ions that are observed in the PIS and CNLS.
- The complete process can be repeated using the product ions and the neutral losses from the spectra of each of the metabolites.

Figure 5.3 General strategy for metabolite identification using tandem mass spectrometry.

some idea of the site of metabolism, it should be kept in mind that MS is generally unsuitable for distinguishing positional isomers (except for isomers with functional groups on different rings), stereoisomers, and enantiomers, so the support of other separation and spectral techniques is essential.

The MS/MS capability, the precursor ion scanning mode, and the constant neutral loss scanning mode of a triple quadrupole mass spectrometer are frequently used for metabolite identification in addition to the full scan [61–63]. As previously mentioned, this approach makes use of the fragmentation pattern of the parent molecule and its fragment ions or neutral losses to detect metabolites. Hence, it is more selective in metabolite scouting than the full (LC-MS) scan approach and is useful in detecting some unknown metabolites. The process to identify metabolites by precursor ion or constant neutral loss scanning is depicted in Fig. 5.3.

In such an analysis, the first step is to get an MS/MS spectrum of the parent drug and select appropriate precursor ions, or neutral losses are into the acquisition methods. In order to cover a variety of metabolites, multiple LC-MS runs are often conducted, each of which follow few specific precursor ions or neutral losses. Like in the full scan approach, the first identification of the metabolite is made by comparison of the masses of drug-related peaks in the ion chromatograms with the mass of the parent. In order to confirm the structures of these metabolites, these runs are always followed by an MS² product scan for each metabolite for further confirmation. The uncommon metabolites that are detected by this method are directly subjected to PI scan for further identification. The method is very useful in detecting certain commonly encountered conjugative biotransformation pathways (glucuronide and sulfate conjugates) that often undergo common cleavages to generate specific neutral fragments, notably the CNL of 176 mass units and the loss of 80 mass units for glucuronide and sulfate conjugates, respectively, under CID conditions. The method has also been commonly used in the detection of GSH conjugates (CNL of 129 in a positive ion mode, formed by cleavage of the pyroglutamic moiety from the GSH conjugate or PIS of m/z 272 in a negative ion mode) of reactive metabolites that are formed via bioactivation of the parent drug or its metabolites. Although precursor ion and constant neutral loss scanning methodology is undoubtedly more selective, its success in increasing the number of detected metabolites still relies to some extent on the ability of the analyst to predict the metabolic pathways of the compound under analysis. Although advantageous over the full scan, the multiple steps of these processes can hamper the throughput, which is sometimes required in the drug discovery arena, especially when there is limited sample available. To detect both common and uncommon metabolites, the use

of a combination of ion-trap instruments and triple quadrupole instruments has been recommended.

Owing to scanning capabilities of triple Q-trap instruments into a single platform, the Q-trap mass spectrometer enables one to use CNLS, PIS, or MRM scan as a survey scan to trigger several new data-dependent scanning modes in the third quadrupole [64]. These include enhanced full mass scan (EMS), EPI scan, enhanced resolution scan, enhanced multiply charged scan, MS³, and time-delayed fragmentation. The term *enhanced* is used to indicate that the data are generated in the ion-trap mode with improved performance. Thus, these hybrid triple Q-trap mass spectrometers clearly provide increased metabolite screening capability compared to traditional ion-trap or triple quadrupole instruments. No follow-up PI experiments are required. This not only increases the throughput but also generates more information from limited sample. The MS/MS survey-scanning capabilities have been utilized for rapid detection and characterization of several phase I and II metabolites [37]. Owing to superior sensitivity and selectivity of the MRM method and automatic acquisition of high quality MS² spectra by EPI, the MRM-EPI scanning method has been successfully applied to rapid screening and characterization of oxidative metabolites. However, the design of this experiment depends on the ability of a scientist to predict biotransformation pathways in advance and also predict the PIs of these metabolites using the fragmentation pattern of the parent. The effectiveness of oxidative metabolite screening by MRM is dependent on the right selection of theoretical metabolite. More recently, to overcome some of the limitations of the MRM method, the multiple ion monitoring coupled to the EPI mode (MIM-EPI scanning mode) has been applied to oxidative metabolite profiling [65]. In an MIM experiment, the collision energy is greatly reduced to the minimal to avoid fragmentation. The MIM experiments offer several advantages over MRM in that it allows the identification of metabolites that would have been missed due to incorrect prediction of an MRM. It is also evident that MIM-EPI had comparable sensitivity and selectivity to those of MRM-EPI.

The task of metabolite identification has been greatly facilitated by the advent of high resolution LC-MS technology. These instruments allow for the determination of molecular formulae and PI formulae with minimal uncertainty. Recently, an MDF technique (also referred to as *fractional mass filtering*) was developed for detecting drug metabolites via postacquisition processing of high resolution LC-MS data [66]. The approach attempts to discriminate metabolite ions from matrix ions based on the similarity of the mass defect values of a drug and its metabolites. This capability to detect predictable and unpredictable metabolites avoids the need for the biotransformation list that is otherwise needed to assure if the ion detected is in fact due to a drug-related peak and has changed the role of high resolution MS in drug metabolite profiling.

Mass defect is defined as the difference between the exact and nominal molecular weights of a molecule. The concept of MDF is based on the fact that the majority of drug substances exhibit a negative mass defect relative to endogenous background constituents of biological samples with a similar molecular weight. This is because the fractional mass of a molecule (the figures after the decimal point) is strongly influenced by the number of hydrogen atoms in that molecule. Drug substances tend to be relatively deficient in hydrogen atoms due to the prevalence of heterocycles and other centers of unsaturation and therefore have different fractional mass defect values than endogenous substances. The mass defect values of most metabolites will be in the similar range (<50 mDa) to that of the parent. For example, hydroxylation changes the

Figure 5.4 Schematic for detection and characterization of metabolites using mass defect filter technique following high resolution mass spectrometry [66].

mass defect by -5 mDa, dehydrogenation by -16 mDa, demethylation by -23 mDa, glucuronidation by $+32$ mDa, and sulfation by -43 mDa. Therefore, this method can quickly filter out masses of drug-related peaks from a complex medium.

Since most phase I and II biotransformation reactions result in shifts in mass defects by <50 mDa, a mass defect window of ± 50 mDa is generally used in this method. The general strategy used for detecting metabolites using the MDF approach is depicted in Fig. 5.4.

There are cases, however, where the molecular ions of the metabolites undergo changes of >50 Da. These include metabolites with significantly different molecular masses than the parent drug that are generally formed via cleavage of the parent drug (such as *N*- or *O*-dealkylation). For example, the mass defect values of nefazodone (NEF; MH^+ 470.2323) and its major metabolite, 1-*meta*-chlorophenylpiperazine (*m*-CPP; MH^+ 197.0845), are 148 mDa apart. Similarly, conjugation with polar molecules such as GSH results in molecular masses that are sometimes significantly greater than the parent drug. Likewise, a dehalogenation reaction of a multihalogenated parent drug can also result in significant mass shifts, especially since the presence of one or more halogen atoms in the parent drug further enhances the negative mass defect of metabolites relative to endogenous materials. Such biotransformation pathways will result in mass defect differences that are $>\pm 50$ mDa and are likely to be missed when a mass defect filter of ± 50 mDa is used. To overcome this obvious deficiency, an improved strategy has been developed in which templates of MDFs

have been generated based on (i) the structure of the drug, (ii) the core substructure of the parent drug, and (iii) the conjugates of the drug [67]. While the MDF template of the parent drug helps detect metabolites that have undergone relatively minor changes in their molecular masses, the substructure filter template, which uses one or a few core substructures of a drug as filter templates, can be applied to detect metabolites that are significantly smaller than the parent drug. Most of the metabolites that can be readily detected using the parent drug MDF template are formed via oxidation, reduction, and dealkylation of a small aliphatic group (<50 Da). While metabolites that are generated via hydrolysis, dealkylation, and other biotransformation reactions that cleave the parent drug into two smaller molecules can be detected by the substructure filter template. The conjugate filter template uses typical drug conjugates as filter templates and is designed to detect different classes of conjugated metabolites. For example, the glucuronide conjugates of the parent and/or hydroxylated metabolites can be detected using a filter based on the glucuronide of the drug. In addition to the three common templates of MDFs described above, some atypical filter templates can be designed for analyzing components such as an active moiety of a prodrug [67]. Additionally, filters that can detect oxidatively dehalogenated metabolites have also been designed. Following detection of these potential metabolites, information on their molecular structures may be extracted from MS/MS spectra with the benefit of the elemental composition information encoded in the accurate masses of their respective parent and fragment ions. More recently, a mass defect-triggered data-dependent MS/MS scanning technique has been developed for selective acquisition of metabolite data with a high resolution mass spectrometer [67].

Several other postacquisition data filtering methods such as NLF or PIF based on metabolite fragmentation patterns obtained from MS/MS spectral data that are acquired using data-dependent MS/MS acquisition methods with linear ion-trap, triple Q-trap, Orbitrap, and QTOF instruments have been developed for finding both common and novel metabolites. For example, LTQs have recently been employed for screening GSH adducts by processing the acquired MS/MS data with NLF of 129 Da in the positive mode and PIF of m/z 272 in the negative mode [68,69]. To increase the detection sensitivity of low levels of metabolites in some complex biological samples, the detection of metabolites is sometimes facilitated through postacquisition data processing with either MDF alone or a combination of MDF and other data mining techniques. For instance, multiple postacquisition data mining techniques were used in parallel for the detection and characterization of *in vitro* metabolites of indinavir.

A so-called all-in-one analytical procedure has been proposed recently for metabolite identification, in which analytes that are separated by UPLC are introduced into QTOF for structural analysis [70–72]. A typical setup utilizes two different data high mass range acquisition functions one with low and one with high collision energy settings and both without MS/MS precursor ion selection. Using this so-called MS^E (where E represents collision energy) approach, both molecular ion and nonselective MS/MS fragment ion data are obtained for all detected compounds, each to separate data acquisition files, and the molecular ions and their fragment ion data can be linked by their retention times. The major advantage of the MS^E methodology is its suitability for coupling with UPLC for short run times and better chromatographic separation, which has been proved to be very useful in high throughput profiling of *in vitro* metabolites in lead optimization. Another promising strategy for parallel use of multiple postacquisition data mining techniques is the application of MDF in combination with

MS^E experiments for fast metabolite analysis. In this approach, full scan accurate mass data sets are processed both with MDF and with narrow and wide EIC combined with control sample comparison, respectively, for the discovery of both common and uncommon metabolites. The MS/MS data acquired with the MS^E scanning can also be utilized for data mining via PIF and NLF as well as for reconstruction of PI spectra of metabolites.

5.3.4 Other Strategies for Metabolite Identification

Most often, MS alone is insufficient to provide the precise structure of metabolites. First, an excess of endogenous material in biological samples often suppresses the ionization of drug-related material complicating metabolite identification by MS. Second, the metabolite can be too polar or too small in size, which can make its identification difficult. In these cases, multiple analytical and wet chemistry techniques, such as chemical derivatization, enzymatic hydrolysis, and hydrogen/deuterium exchange (H/D exchange) combined with MS, are helpful to probe novel and isomeric metabolites of drug candidates [27,44].

5.3.4.1 Chemical Derivatization. Derivatization techniques combined with LC-MS/MS have proved to be very powerful tools for the characterization and quantification of novel and unusual metabolites. This technique can supplement metabolite identification by increasing sensitivity (especially those metabolites that are poorly ionized) and lipophilicity (improvement in retention and separation) of the metabolites. Tremendous structural information can also be obtained for drug metabolites by analyzing MS/MS data before and after chemical intervention. Most importantly, chemical modification of these metabolites can lead to derivatives with characteristic fragmentation. Further, the use of chemical derivatization of low molecular weight compounds to improve their detection characteristics for chromatographic analysis is also well documented [44]. For example, derivatization of the phenolic OH of ethinylestradiol with dansyl chloride by introducing a basic nitrogen significantly increases the ionization efficiency in ESI/MS for pharmacokinetics studies.

Several chemical reactions have been used in identifying metabolites of drugs when the mass spectrum does not offer further confirmation of the sites [44,73–75]. Some reactions include oxidation of alcohols with mild oxidizing agents such as potassium dichromate and sulfuric acid (Jones reagent), pyridinium chlorochromate (PCC), pyridinium dichromate (PDC, Cornforth reagent), reduction of ketones with sodium borohydride and *N*- and *S*-oxides with $TiCl_3$, alkylation with diazomethane; and esterification with methanolic hydrochloric acid. These relatively simple chemical modifications can confirm the site of metabolism especially in molecules where regioisomers and isobaric metabolites are possible. For instance, the site of metabolism on the secondary versus the primary carbon center of an aliphatic ethyl chain in pioglitazone was easily determined by oxidation with Jones reagent (Fig. 5.5) [76]. Such a reaction converted the secondary alcohol to a ketone and the primary alcohol to a carboxylic acid.

Analysis of products of these reactions can help differentiate the regioisomers and pinpoint the site of modification since the formation of a ketone will reduce the molecular ion by 2 amu, while the formation of the carboxylic acid will increase the mass of the molecule by 14 amu. Similarly, selectivity of reagents toward a particular functional

Figure 5.5 Oxidation of pioglitazone metabolites with Jones reagent [76].

group can be used to differentiate and identify the type of modification. For instance, acyclic amine moieties such as piperidines or pyrrolidines in a molecule can undergo P450-mediated oxidation to piperidones or lactams. Both these pathways result in addition of 14 amu to the motif. A differentiation of a ketone formation versus a lactam (addition of 14 amu to the molecular ion of the parent drug) formation following oxidation of an alicyclic amine can be made by treatment of the sample with sodium borohydride (Fig. 5.6). Treatment with sodium borohydride can reduce ketones to alcohols, thus increasing the molecular ion of the product by 2 Da. On the other hand, there is no change in the molecular weight of the lactam since these functionalities are not affected by these reducing reagents. Alternatively, the two functionalities can be distinguished by treatment of the mixture with hydrazine or methoxylamine. Conversion of the carbonyl functionality in the ketone to a hydrazone can readily differentiate the lactam from the ketone.

Methods to distinguish formation of *N*-oxides from sulfoxides and *C*-hydroxylations could have a significant impact on the rapid metabolite identification/profiling of drug molecules by MS. Kulanthaivel *et al.* have developed an efficient and a simple method to selectively convert *N*-oxides to their corresponding amines [77]. Their work demonstrated TiCl_3 to be a facile and easy-to-use reagent in the presence of biological matrices that could selectively reduce *N*-oxides in the presence of other labile groups. Prakash *et al.* [78] have also used aqueous titanium chloride to reduce a sulfoxide metabolite of a sulfur-containing drug. This led to the disappearance of the sulfoxide peak and appearance of another metabolite peak, the methyl sulfide (Fig. 5.7). This led the group to conclude that the former was a sulfur oxidation product of the latter.

Alkylation with diazomethane or diazoethane to the corresponding ether has been used to characterize the phenolic hydroxyl and carboxylic acid functionalities from the aliphatic hydroxyl groups. The use of diazoethane for derivatization proved to be

Figure 5.6 Derivatization of the ketone with hydrazine or methoxylamine.

Figure 5.7 Reduction of *N*-oxides and sulfoxides with titanium trichloride.

useful in elucidation of the locality of the phenolic OH group in structures of the metabolites, for instance, RWJ-26240 [79]. Introduction of a methyl moiety into a carboxylic acid can also be accomplished by treatment of the sample with methanolic hydrochloric acid ($\text{CH}_3\text{OH}/\text{HCl}$). However, this method cannot methylate phenolic or aliphatic hydroxyl groups in the molecule. This selectivity can be used to differentiate between a carboxylic acid functionality and a phenolic or aliphatic hydroxyl groups in case isobaric metabolites are formed. The conversion of the molecule to a nonpolar methyl ester also changes its retention time in the chromatogram in addition to the

increase of 14 amu in the mass spectra. Methylation was also used to identify the site of glucuronidation for traxopodil [80]. On the same lines, Schaefer *et al.* [81] have demonstrated the use of a selective acetylation strategy to elucidate the positions of glucuronidation of carvedilol. The approach relies on the selective acetylation of hydroxyl and amine groups under different conditions. Nucleophilic groups such as amines and hydroxyls are readily acetylated in nonaqueous solution by acetic anhydride in the presence of a base (such as pyridine). In aqueous solution, however, the more nucleophilic amine groups are rapidly acetylated by acetic anhydride, while acetylation of hydroxyl groups is prohibited due to the presence of water. The site of modification can therefore be identified from the number of acetyl groups that are added into the molecule. Thus, addition of number of acetyl groups in carvedilol in the nonaqueous media indicated the site of glucuronidation of this molecule.

Differentiation of aromatic hydroxyl group from an aliphatic hydroxyl group can also be made by treating the biological sample with acetic anhydride [44]. Under these conditions, the sample is treated with sodium bicarbonate solution and acetic anhydride. Phenolic hydroxyl groups can be acetylated selectively in the presence of aliphatic hydroxyl groups by acetic anhydride in water at pH 9–10. Hence, an addition of 42 amu to the molecule and a subsequent shift in the retention time can readily differentiate between the two hydroxy groups. An alternative derivatization that is specific for phenols (also useful for amines) is the reaction with 5-(dimethylamino)naphthalene-1-sulfonyl chloride (dansyl chloride), which forms a sulfonate in the aqueous alkali [73]. Given the ability of the derivative to be protonated in the acidic medium, this reaction has been useful in enhancing the ionization of otherwise nonionizable metabolites in addition to discriminating the aliphatic and aromatic hydroxyl groups.

The hydrolytic cleavage of ester under alkaline conditions is a reaction that is commonly used to distinguish an acyl glucuronide from an ether glucuronide (Fig. 5.8). The use of this reaction is based on the fact that esters are readily hydrolyzed by aqueous alkali, while the aliphatic and/or aromatic ethers are resistant to hydrolytic cleavage in the alkaline medium and require harsh conditions. Thus, regeneration of the parent drug on treatment of aqueous alkali confirms that the conjugate is an acyl glucuronide. Thomas *et al.* [82] described the differentiation of acyl- and *O*-glucuronides by hydrolysis with β -glucuronidase and sodium hydroxide in studies on metabolism of gemfibrozil.

A chemical reaction is regularly employed to identify reactive metabolites formed via bioactivation of xenobiotics [83–85]. This helps in the elucidation of plausible

Figure 5.8 Saponification of ester versus ether glucuronide conjugates.

Figure 5.9 Reaction of reactive intermediates with glutathione and cyanide.

intermediates and their potential mechanism of formation and helps in designing new compounds that are devoid of this liability. Several nucleophilic trapping agents have been employed to scavenge these intermediates (Fig. 5.9). Addition of thiol reagents such as GSH or *N*-acetylcysteine in *in vitro* incubation is most commonly used for trapping reactive intermediates, making them amenable to characterization by MS. In cases where reactive metabolites cannot be trapped by GSH, other means have been used in the characterization of these intermediates. For instance, cyclic amines are known to undergo two electron oxidation to imines or iminium ions. These intermediates can also modify proteins via a covalent reaction between the intermediate and the macromolecule. Despite their electrophilicity, these intermediates do not react with GSH (because of their potential instability). However, these intermediates are readily trapped by cyanide anion following addition of potassium or sodium cyanide [86]. The corresponding aminonitrile adduct formed by the reaction between the iminium intermediate and the cyanide anion results in addition of 26 mass units to the molecule, which can be readily characterized by MS.

Similarly, the ring opening of heteroaromatic rings such as the furans to dienols has been determined by treatment of the incubation mixture with semicarbazide or methoxylamine [87,88]. For instance, metabolism of L-739,010, a 5-lipoxygenase inhibitor, containing a furan ring, undergoes oxidative ring opening to form a reactive 2-butene-1,4-dialdehyde intermediate [89] (Fig. 5.10). This intermediate can covalently bind to proteins via nucleophilic addition to the aldehyde groups or Michael addition to the carbon–carbon double bond. Indeed, addition of methoxylamine dramatically reduced the extent of covalent binding. In the presence of methoxylamine, several *O*-methyloximes were generated and characterized by LC-MS/MS and ^1H NMR analysis. Many of the chemical derivatization methods documented for chromatographic analysis are suitable for ESI MS analysis, and readers should not be limited to the types of reaction discussed in this review.

5.3.4.2 Hydrogen/Deuterium Exchange. Hydrogen/deuterium exchange is a strategy widely used in studying protein structures or used for elucidation of mass spectral fragmentation mechanisms. However, in recent times, it has proved itself to be useful in metabolite identification studies, especially in cases where alternative structures

Figure 5.10 Derivatization and trapping of reactive metabolites following oxidation of furan-containing compounds.

for an observed biotransformation are possible [44,90–92]. As described previously, metabolism of xenobiotics involves functionalization of polar groups (e.g., $-\text{OH}$, $-\text{SH}$, $-\text{NH}$, $-\text{NH}_2$, and $-\text{CO}_2\text{H}$), thus increasing the number of exchangeable hydrogen atoms. These labile, exchangeable protons can be replaced with deuterium (D) isotope in the presence of deuterated solvents or reagents. The resulting deuterated molecule shows an increase in its m/z value in comparison to a nondeuterated molecule. The difference in the m/z value of the deuterated and a nondeuterated compound facilitates the determination of the presence, number, and position of H/D exchangeable functional groups within a metabolite and serves as an aid in its structure elucidation. In addition, H/D exchange experiments facilitate the interpretation of MS/MS fragmentation processes. For example, this approach was applied successfully to differentiate N -oxides, sulfoxides, and epoxides from monohydroxylated metabolites and sulfones from dihydroxylated metabolites. Even though the increase in mass of N -oxide, a sulfoxide, or the epoxide is similar to that of a hydroxylated metabolite, the former functionalities do not contain an exchangeable proton like the hydroxyl group. Although some information is obtained from the mass spectrum of the three metabolites, treatment with a deuterated solvent provides proper confirmation of the functionality that is incorporated. This is because such a treatment with result in a mass shift of the hydroxylated compound by 2 amu, sulfoxide by 1 amu, while no change in the mass shift of N -oxide is observed. H/D exchange experiments can be performed online, where either a deuterated solvent is used as the LC mobile phase or a deuterated reagent gas is used or by postcolumn infusion of deuterium oxide into a normal LC-MS run. The use of deuterium oxide as the regular chromatographic LC-MS mobile phase for studying drug metabolism has been reviewed recently [93].

5.3.4.3 Enzymatic Hydrolysis. Enzymatic hydrolyses of metabolites especially phase II conjugates have also proved useful in their identification/confirmation of these conjugates, especially when the conjugates have poor ionization efficiency. The presence of any phase II metabolite in the biomatrix can also be verified using xenobiochemical experiments with β -glucuronidase and/or arylsulfatase [94,95]. These two enzymes are able to quite selectively and quantitatively cleave the ether or ester bond between glucuronic or sulfuric acid and the xenobiotic part of the phase II drug metabolite under the back-formation of the phase I drug metabolite. Comparative

HPLC analyses of the sample incubated without an enzyme and the same sample after enzymatic treatment using β -glucuronidase and/or arylsulfatase afford qualitative and quantitative information about phase I and II drug metabolites in the biological sample. In some instances, the enzymatic hydrolysis of the conjugates proves difficult. For example, when a compound containing a carboxylic acid undergoes glucuronidation, it tends to undergo acyl migration. These rearranged products are very weak substrates of β -glucuronidase and therefore do not undergo the desired cleavage. In such cases, the advantage of susceptibility of the site of glucuronidation to a chemical reaction (described above) can be helpful in further confirming the presence of an acyl glucuronide in the molecule.

5.3.4.4 Stable Isotope Labeling. Stable isotope-labeled compounds have been synthesized and effectively utilized by drug metabolism scientists and toxicologists to gain better understanding of drugs' disposition and their potential role in target organ toxicities [96–98]. The combination of stable isotope-labeling techniques with MS and NMR spectroscopy allows rapid acquisition and interpretation of data and has promoted greater use of these stable isotope-labeled compounds in ADME studies. MS has a unique capability to separate stable isotopes, which can be utilized in a large number of applications. Some stable isotopes that have been utilized for identification purposes are ^1H and ^2H (D), ^{12}C and ^{13}C , ^{14}N and ^{15}N , ^{16}O and ^{18}O , and ^{32}S and ^{34}S . In cases where the compound includes one or more Cl or Br atom, an incorporation of a stable isotope is not necessary. The principal isotopes of ^{35}Cl and ^{79}Br are ^{37}Cl and ^{81}Br . These two atoms will display abundant $M + 2$ ions in the mass spectra with known abundance ratios ($\sim 25\%$ for ^{37}Cl and $\sim 50\%$ for ^{81}Br). In metabolism studies, a method called *isotope cluster* technique where a 1:1 mixture of labeled and unlabeled drug is administered and analyzed by LC-MS is generally employed to detect metabolites. Following processing and analysis of the samples, the peaks that show an isotope cluster with known mass difference are detected. Usually, a separation of >2 amu between the two ions is desirable, which leads to the appearance of a twin ion pair pattern for the parent compound and its metabolites in the mass spectra of the biological extracts. The identification of a metabolite should fulfill the following criteria:

1. Two peaks with identical shapes and retention times must be recorded in the ion chromatograms.
2. The mass difference of the two peaks must be the same as the mass difference between the labeled and the unlabeled parent drug.
3. The relative abundance ratio of the peaks must be the same as the concentration ratio of the labeled and the unlabeled parent drug.

Computer programs have been developed to identify potential metabolites by searching each scan of a chromatographic run for the characteristic isotope cluster of the parent compound mixture. Numerous examples exist in the literature where investigators have used this technique to study *in vitro* and *in vivo* metabolic disposition of compounds [98].

Besides locating metabolites in biological matrices, the stable isotopes can be particularly useful in determining the structures of unusual or unpredictable metabolites formed from compound. The benefit of isotopic labeling here is fragmentation pattern

recognition. This exercise can give information about the potential site of modification, especially when the molecule produces a same fragment ion following cleavage of the molecule. When the labeled part of the molecule is retained during the fragmentation, the fragment ion maintains the isotopic difference introduced by labeling. However, if the labeled moiety is lost, the m/z value of both the labeled and the nonlabeled fragments are identical.

The incorporation of stable isotopes into compounds also permits delineation of possible mechanisms and the enzymes responsible for the formation of particular metabolites. Isotopically labeled oxygen or water, $^{18}\text{O}_2$, or H_2^{18}O , have been frequently used for this purpose. For example, replacement of $^{16}\text{O}_2$ with $^{18}\text{O}_2$ in an *in vitro* incubation allows the incorporation of ^{18}O in the metabolites that are formed oxidatively. Conversely, in some cases, H_2^{18}O has been used in the incubation mixtures to assess whether the oxygen incorporated into the metabolite is derived from water. This type of experiment not only allows for assessing the fate of oxygen incorporated into the molecule (from air or a water molecule) but also helps delineate the enzyme that can catalyze this oxidation. For instance, enzymes such as monoamine oxidase (MAO), flavin monooxygenase (FMO), or P450 use air as a source of oxygen to oxidize the compound, while the source of oxygen in aldehyde-oxidase-catalyzed reactions is water. Such mechanistic information about metabolite formation and the enzymes involved is very valuable in the early discovery studies.

Stable isotope labeling does not necessarily have to be performed on the compound whose metabolism is being studied. At times, moieties (e.g., GSH) that are eventually incorporated into the compound of interest may be labeled with stable isotopes so that the products can be identified as metabolic products. The use of stable isotope-labeled GSH to trap and characterize *in vitro*-generated reactive metabolites is an example of this approach [98].

5.4 NMR SPECTROSCOPY

As stated earlier, the structure of a metabolite is critical to the development of a pharmaceutical compound and can play an important role in understanding its toxicology, enzymology, or biotransformation pathways. Beyond the normal challenges of structure elucidation, metabolites are typically only available at low levels ($\mu\text{g/mL}$ or less) and are contained in very complex matrices such as blood, excreta, or tissue. While MS is very valuable in structure elucidation, there are situations where MS data alone can fail to definitively elucidate a metabolites structure. In these instances, other spectroscopic techniques need to be employed. One of the most powerful of these techniques is NMR spectroscopy.

Since its inception in the late 1940s, NMR spectroscopy has grown to be arguably the most valuable analytical tool for unambiguous structural characterization. NMR data provides information on the number of nuclei within a compound as well as the microchemical environment of each nuclei through chemical shift and connectivity information through coupling constants [99]. This diversity of information makes NMR data, when used in conjunction with MS data, a very useful structural elucidation tool.

While NMR is an incredibly powerful technique, it does have limitations, largely in the area of sensitivity. Only specific nuclei are NMR active, those with a quantum spin of $1/2$ [100,101]. Hydrogen (^1H), carbon (^{13}C), nitrogen (^{15}N), and fluorine (^{19}F)

are perhaps the most useful NMR-active nuclei to a drug metabolism scientist. The sensitivity of experiments targeting these nuclei, in some cases, is further limited by the lack of an abundant active isotope. As an example, the NMR-active nucleus of carbon is the ^{13}C isotopic form, which is only 1.1% of the total carbon pool. Obviously, this limits the sensitivity of experiments utilizing this nucleus.

In the past 15 years, many advances have been made to overcome this relative lack of sensitivity. New hardware incorporating cryoprobes, NMR probes with small cell volumes, and higher field instruments have increased NMR sensitivity dramatically [102,103]. Additionally, new more sensitive pulse sequences have enhanced the ability to establish structural connectivity through long-range heteronuclear (^1H - ^{13}C and ^1H - ^{15}N) correlations [104–106].

Another limitation of NMR, when performing experiments for metabolite structural elucidation, is the need for pure sample. The need for an isolated sample has long been a stumbling block for drug metabolism scientist. Although there has been significant improvement in preparative chromatography columns and HPLC systems, it is still a considerable effort to isolate a pure metabolite from biological matrix. An alternative to preparative isolation is LC-NMR, where in much the same manner as LC-MS, an NMR spectrometer is interfaced with a chromatography system. While this has great potential, it is not a panacea. Solvent suppression, column loading, and computer automation can all be problematic. However, when a metabolite is unstable or recalcitrant to isolation, HPLC-NMR may be the best option for acquisition of meaningful NMR data [107,108].

Discussed in this section is the use of NMR in structural elucidation of drug metabolites. It is important to distinguish NMR application to drug metabolite identification from its application to metabonomics. Metabonomics is the study of whole system's biology using biomarkers, and although NMR and LC-NMR may be used in support of biomarker identification, metabonomics is a separate discipline from metabolite structure elucidation [109–111].

5.4.1 Sample Preparation for NMR Spectroscopy

The successful structural elucidation of a metabolite starts well before the acquisition of NMR data; it begins with the design of the sample generation experiment. Obviously, the amount of metabolite generated in these experiments is critical, and also important is the matrix and the subsequent ease of metabolite isolation. If the compound of interest can be generated in sufficient quantities using *in vitro* systems such as liver microsomes, other subcellular fractions, hepatocytes, or individually expressed recombinant drug-metabolizing enzymes the isolation is typically more efficient. When *in vitro* generation systems are used, off-line isolation can sometimes be eliminated with the use of LC-NMR (see section below). In other cases, where the *in vitro* turnover rate of the parent compound is low, dosing an animal of appropriate species may generate metabolite quantities in sufficient amount such that using urine or bile as a starting matrix may be the most expeditious route to a pure sample. Excipients used in the dose formulation or *in vitro* incubation should also be considered. Glycolic polymers, which are commonly used in dosing solutions and enzymatic preparations, chromatographically separate into individual components with a wide variety of polarities. Frequently, these compounds have no UV chromophore making them invisible, until either MS or NMR are used to analyze the sample. The combination of these two traits makes the isolation of pure low

level metabolites difficult when these types of compounds are present. Consequently, if there are alternatives to the use of these polymers, they should be pursued.

In the case of an *in vivo* study, sample collection strategies can strongly influence the amount and quality of the metabolites generated. Which matrix to use, whole blood, plasma, urine, bile, or feces, should be considered. Clearly, the metabolite concentration will vary depending on the matrix and the time of collection. Some matrixes may contain endogenous materials that interfere with the chromatographic separation of the metabolite of interest. Sample stabilization may also be critical. Some metabolites are unstable under certain pH conditions, and the collection should be made to optimize the stability of the isolate. As an example, acyl glucuronides, to varying degrees, are prone to migration under neutral and basic conditions. In order to stabilize these metabolites, samples should be made acidic as soon as collected to ensure the highest concentration of the O-1 β -glucuronide [112–114].

The isolation of metabolites for NMR analysis using SPE and preparative chromatography has been the standard for many years. In general, the procedures are relatively similar (Fig. 5.11). The matrix is clarified through either protein precipitation and/or centrifugation. Portions of the clarified solution are loaded onto a reversed-phase SPE column, and fractions are eluted using increasing percentages of organic solvent, in general, acetonitrile or methanol. Aliquots from these SPE fractions are profiled via LC-MS. Once the fractions containing the metabolite of interest are identified, they are evaporated to dryness and reconstituted in a mixture of aqueous and organic in preparation for chromatographic separation [115,116]. Chromatographic isolation of a metabolite can be performed on any size HPLC column; typically, this is performed on a column with a 10-mm diameter using flow rates of approximately 5 mL/min. The chromatographic analysis may be either isocratic or gradient depending on the complexity of the separation. Fractions are collected based on UV or MS output from the

Figure 5.11 General scheme illustrating the isolation of metabolites from biological matrices for NMR analysis. (See color insert.)

TABLE 5.2 Resonances From Residual Protonated Solvents Typically Used in NMR Spectroscopy

Solvent	¹ H		¹³ C		H ₂ O	Comments
	Chemical Shift	Multiplicity, Coupling Constant	Chemical Shift	Multiplicity, Coupling Constant	Chemical Shift	
D ₂ O	4.80	s	—	—	4.80	Contains exchangeable hydrogens
DMSO	2.50	5, <i>j</i> = 1.9 Hz	39.5	7, <i>j</i> = 21.0 Hz	3.30	Contains exchangeable hydrogens
Methanol	3.31	5, <i>j</i> = 1.7 Hz	49.2	7, <i>j</i> = 21.4 Hz	4.78	
Acetonitrile	4.78	s	—	—	2.1	
	1.94	5, <i>j</i> = 2.5 Hz	1.4 118.7	7, <i>j</i> = 21.0 Hz s		
Chloroform	7.24	s	77.2	3, <i>j</i> = 32.0 Hz	1.5	
Acetone	2.05	5, <i>j</i> = 2.2 Hz	29.2 206.7	7, <i>j</i> = 19.4 Hz s	2.8	

preparative system. Final fractions should be checked for purity and then the sample exhaustively dried before NMR analysis. This method produces a high concentration and quality sample. Even if the final purification step is in line with LC-NMR, this SPE sample preparation is highly recommended.

The final consideration in sample preparation is solvent choice. For NMR operational reasons, all solvents used must be deuterated. The isolated metabolite must be soluble in the chosen solvent. Generally, if the parent compound is readily soluble in a given solvent, this solvent will also be a suitable choice for the isolated metabolite. Dimethyl sulfoxide, methanol, and acetonitrile are usually adequate for solubilizing most metabolites. Impurities in the solvent should also be considered. Resonances from residual protonated solvents (e.g., CD₂HOD in CD₃OD) will be the largest nonsample-related resonance in the spectrum (Table 5.2). To avoid these impurities, the best available solvent should be used. Most vendors offer deuterated solvents of “100.0% grade.” This grade should be used for any critical NMR analysis. Last, the locations of the residual solvent and water lines should be considered. If the molecules of interest, parent and metabolite, have resonances critical to the structure solution that could be interfered with by either the residual solvent or water resonances, a different solvent may make the data interpretation more straightforward.

5.4.2 Nuclei

While most other spectroscopic techniques evaluate the response of an entire molecule (MS, IR, and UV), NMR response is centered around individual classes of nuclei. Each family of nuclei will have different physical and quantum characteristics that make them unique. These differences dictate the class of experiment that can be performed and the type of information that can be gleaned from each experiment. For the drug metabolism scientist, there are a limited number of relevant elements that are NMR active.

5.4.2.1 ^1H -Hydrogen. Without question, the most useful nuclei for metabolic studies is ^1H . It is present in almost all organic compounds of interest; endogenous or xenobiotic. The NMR-active form is essentially 100% naturally abundant and is the most sensitive of all common nuclei. Limits of detection for most modern high field instruments are in the low nanomole range for directly observed experiments. The chemical shift range is relatively small (0–13 ppm), which can lead to overlapping resonances. ^1H - ^1H coupling can cause further complication of the spectra, but may also be used to delineate the structure of unknown metabolites through the judicious interpretation of coupling constants and patterns. One of the largest difficulties with ^1H NMR is the ever-present interference from endogenous compounds, which necessitates the isolation of the metabolite for spectroscopic characterization. This may be done before NMR analysis using a variety of separation science techniques (see above). Alternately, this isolation may be performed in line with these same separation techniques directly coupled to the NMR system.

5.4.2.2 ^{13}C -Carbon. ^{13}C NMR data can be critical to the elucidation of a metabolite structure. Establishing the number of carbon atoms and their multiplicity (C, CH, CH_2 , and CH_3) in an unknown metabolite, in conjunction with ^1H data, can provide key information in the structural elucidation process. Directly observed ^{13}C data are usually acquired with ^1H decoupling resulting in single resonances for each carbon atom. The spectra for these experiments are relatively clean and easy to interpret. ^{13}C has a wide range of useful chemical shifts, 0–220 ppm, limiting the opportunity for overlapping resonances. However, the low native sensitivity (approximately 25% that of ^1H) and the low natural abundance (1.1%) usually preclude the direct acquisition of meaningful ^{13}C data on isolated metabolites. These sensitivity issues can be surmounted by the use of indirect heteronuclear 2D experiments, which are discussed in detail below.

5.4.2.3 ^{19}F -Fluorine. ^{19}F NMR data is very useful as a tool to determine the distribution, both quantitatively and qualitatively, of metabolites in biological matrixes. As is carbon, direct observed ^{19}F data are usually acquired with ^1H decoupling typically resulting in a single resonance for each individual ^{19}F atom. If the data are acquired appropriately (using a power-gated decoupling pulse sequence), the responses for the resonances within the spectra are quantitative [117–120]. A major advantage of ^{19}F NMR is the lack of interference from endogenous compounds. The spectra width of ^{19}F is in the 200–250 ppm range, providing a broad spectral width for data acquisition. Additionally, the relative sensitivity of ^{19}F is quite high (approximately 83% that of ^1H) and the natural abundance of the NMR-active nuclei is 100%. While there are many advantages of ^{19}F NMR, the obvious requirement of a fluorine atom in the molecule of interest can limit the utility of these experiments.

5.4.2.4 ^{15}N -Nitrogen. Historically, the acquisition of meaningful ^{15}N NMR data from metabolites has been precluded due to the low sensitivity and natural abundance of the nuclei. However, over the past 5 years, with the advent of cryoprobes and indirectly detected experiments, sensitivity levels of ^{15}N experiments have come within reach of the metabolism scientist [121]. ^{15}N data are particularly useful with two classes of metabolites, nitrogen oxidation and nitrogen conjugation. In simple cases, both these types of metabolites can be easily classified by other means. *N*-oxides can be delineated with deuterium exchange experiments or through the use of titanium trichloride

reduction. *N*-glucuronides have characteristic molecular weights and MS/MS fragmentation patterns. Additionally, they are susceptible to enzymatic cleavage. However, in situations where there are multiple N sites available for oxidation or conjugation, these techniques are not sufficient for definitive structural elucidation. This information can be acquired using ^1H - ^{15}N heteronuclear NMR experiments. ^1H - ^{15}N heteronuclear multiple quantum coherence (HMQC)-type experiments (directly bonded H-N) can be used to observe changes in nitrogen chemical shifts and ^1H - ^{15}N heteronuclear multiple bond correlation (HMBC) can be used to establish location through long-range coupling.

5.4.2.5 Other Nuclei. ^2H NMR is limited by negligible natural abundance (0.015%), small spectral width, and that ^2H is a quadrupolar nuclei, which results in broad line shape except for low MW compounds. Despite these drawbacks, in instances where a ^2H label can be inserted in the parent molecule, deuterium NMR can be utilized as an analytical tool. Nicholls *et al.* [122,123] have used ^2H NMR extensively to study futile deacetylation of acetanilides.

Tritium is a particularly sensitive nucleus with an operational NMR field strength at 6% greater than that of ^1H . It also has a chemical shift range and coupling constants close to that of hydrogen making data interpretation familiar. However, this is a radioactive isotope which requires special precautions and monitoring making its ease of use significantly more difficult. Additionally, the natural abundance of ^3H is negligible, hence, requiring a synthetically labeled parent molecule. Despite these obstacles, there are several studies where tritium NMR data have been successfully used to address metabolic questions [124].

5.4.3 NMR Experiments

The theoretical basis of NMR experiments has been discussed elsewhere at length including text for a cursory understanding as well as advanced treatment of the physics of NMR [99,101]. Briefly, certain nuclei, when placed in a magnetic field, behave as individual gyroscopes precessing at a frequency unique to each class of nuclei (^1H , ^{13}C , ^{19}F , etc.). As a pulse of RF energy is introduced into this system, the nuclei achieve an excited state. When the excited nuclei relax to ground state, they generate a decaying sinusoidal signal. This signal is measured in time versus magnitude and is referred to as the *free induction decay* (FID). These experiments are controlled via a computer program called a *pulse sequence* that contains specific instructions that regulate the excitation RF and data acquisition. After acquisition, the FID can then be transformed mathematically from the time domain to the frequency domain using a fast Fourier transformation (FFT). This transformation results in the recognizable and interpretable 1D NMR spectrum.

When 1D experiments fail to provide the structure of a metabolite, data from 2D experiments may grant additional insight. The basic 2D NMR experiment involves the acquisition of multiple 1D data sets with a systematic variation of parameters such that a second dimension of FID is developed. As with 1D data, a fast FT can be applied to the second dimension of data. The Fourier transformation of data in both dimensions results in a 2D data set. The detected dimension (referred to as *F2*) typically contains 1–2k data points. The indirect dimension (referred to as *F1*) typically contains 128–512 data points. In each case, there is dramatically less digital resolution than that in a 1D data set. This limitation in digital resolution should always be considered in experimental selection. There are many excellent reviews of the acquisition of 2D NMR [101,125].

5.4.3.1 1D Pulse Sequences. As reviewed above, the most popular of all NMR experiments is the one-dimensional ^1H experiment. One-dimensional NMR experiments, as the name implies, collect data in a single dimension from a single class of nuclei. The data from this experiment provide information on the number of hydrogen atoms, the individual microchemical environment of each hydrogen, and the proximity of the hydrogen atoms to each other. This information alone is very powerful and in many instances may be sufficient to identify the structure of a metabolite. In Hutzler's work on (1-[(2-ethyl-4-methyl-1H-imidazol-5-yl)methyl]-4-[4-(trifluoromethyl)-2-pyridinyl]piperazine (EMTPP), the α -hydroxyl metabolite was easily characterized by ^1H data (Fig. 5.12) [126]. The ethyl moiety of the parent compound had two resonances: a triplet at 1.25 ppm integrating to three ^1H with a coupling constant of 7.6 Hz (B) and a quartet at 2.64 ppm integrating to two ^1H with a coupling constant of 7.6 Hz (A). In the isolated metabolite (M2), both these resonances have changed, the B to a doublet with a chemical shift of 1.37 ppm integrating to three ^1H with a coupling constant of 6.6 Hz and the A to a quartet with a chemical shift of 4.62 ppm with a coupling constant of 6.6 Hz. These changes can only be accounted for by the oxidation of the α -carbon. There are many other examples in the literature where 1D ^1H NMR data provided critical information to the structure proof of a metabolite [127–130].

Similar 1D data can be collected from other nuclei, most notably ^{13}C . Unlike ^1H spectra, ^{13}C spectra are acquired decoupled. Each carbon atom may be coupled to one or more hydrogen atoms in a given molecule. Because of this heteronuclear coupling, individual resonances within ^{13}C spectra have very complex structure. In order to simplify the 1D ^{13}C spectra, ^{13}C acquisitions are usually performed with broadband decoupling of all protons [99]. The decoupling removes the scalar coupling of the ^1H to the ^{13}C resonances and produces a singlet for each carbon resonance. The condensation of the multiplets to a single resonance also increases the signal-to-noise ratio. Because of the broad range of ^{13}C resonances (~ 230 ppm), one line is typically observed for each carbon atom in the molecule with resonances rarely overlapping. As with ^1H spectra, the chemical shift of each ^{13}C resonance is indicative of its microchemical environment. Because of this, it is possible to identify certain functional groups within a molecule for which there is no direct evidence in the proton spectrum, for example, carbonyls.

There is a wide range of relaxation time for ^{13}C atoms. This makes integration of a typical ^{13}C spectrum inappropriate. However, even with this limitation, the determination of the total number of carbons within a molecule from 1D ^{13}C spectra is easily done. While carbon chemical shift information is often critical to the solution of a metabolite structure, the amount of material required for the acquisition of a directly observed ^{13}C spectra can preclude this type of experiment. Instead, ^{13}C chemical shift data are usually acquired through the much more sensitive indirect ^1H - ^{13}C 2D experiments (see below).

The nuclear Overhauser effect (nOe) experiment is also a one-dimensional experiment. It is unique from other 1D experiments because its data is used to establish through-space interaction between nuclei. This information can be very valuable in establishing either the stereochemistry or regiochemistry of a metabolite. The experiment applies a radio-frequency to a single resonance in the ^1H spectrum, such that the hydrogens at that resonance become saturated. Like any chemical system that has been disturbed, it will attempt to return to a steady state. For the nOe experiment, this adjustment takes the form of redistribution of energy from the saturated nuclei to

Figure 5.12 ^1H NMR data for EMTTP and its metabolite.

nuclei that are spatially close to the irradiated ^1H . An acquired ^1H nOe spectrum can show changes in signal intensities for those ^1H s close in space (usually less than $3 \text{ \AA}$) to the saturated proton.

Data from nOe experiments are particularly useful in connecting ^1H spin systems that are isolated by heteroatoms. In drug metabolism, the classic example is establishing the site of glucuronidation [131–133]. Here, the nOe enhancement from the irradiation of the anomeric ^1H provides information connecting the glucuronic acid to specific moieties of the parent compound [131].

5.4.3.2 2D Pulse Sequences. The most sensitive 2D experiments, and therefore the most useful, are ^1H - ^1H homonuclear pulse sequences. The ^1H - ^1H correlation spectroscopy (COSY) and ^1H - ^1H total correlation spectroscopy (TOCSY) are the first strata of 2D NMR experiments to be performed in the structural elucidation of a metabolite. Each of these methods is based on scalar coupling between ^1H atoms within the same molecule. COSY experiments are optimized for ^1H - ^1H couplings that are 5–12 Hz; typically 2–4 bonds remote from each other. TOCSY experiments are typically optimized for longer range ^1H - ^1H interactions (1–4 Hz) that are three to five bonds remote. Both these experiments provided “nearest neighbor” information through scalar coupling [99,134,135].

A nuclear Overhauser effect spectroscopy (NOESY) also is a homonuclear ^1H - ^1H 2D experiment that is predicated on dipolar coupling (through space). Like its analogous 1D experiment, a NOESY can provide information about a molecule's three dimensional structure and/or its stereochemistry [136,137].

Heteronuclear 2D experiments fall into two categories: one-bond correlation or multiple bond correlation experiments. Within these groups, there are several variations on each theme. One-bond correlation experiments link a given hydrogen resonance with the specific heteroatom resonance (either ^{13}C or ^{15}N) to which it is bonded. There are numerous versions of this type of experiment. The more sensitive ones are ^1H -detected. That is the nucleus that is monitored is the ^1H and the chemical shift of the Carbon is inferred. The ^1H -detected versions are heteronuclear single quantum coherence (HSQC), and heteronuclear multiple quantum coherence (HMQC), each with gradient and/or multiplicity-edited variations. There are also carbon detected heteronuclear experiments, heteronuclear correlation (HETCOR), which are ^{13}C detected. Carbon-13 detected experiments are less useful because of their lack of sensitivity stemming from the low natural abundance (1.1%) of the active carbon form, ^{13}C . However, when there is insufficient resolution in the carbon dimension, a HETCOR may be preferable to either an HSQC or HMQC because of the increased resolution in the ^{13}C dimension. The direct correlation between ^1H and ^{13}C is useful when there are carbon resonances with unusual chemical shifts that could be diagnostic. For example, a methine attached directly to a carbon with a chemical shift greater than 185 ppm indicates an aldehyde function. Another more common example is the metabolic oxidation of a methylene ($\text{X-CH}_2\text{-X}$) to a methine with a hydroxyl (X-HCOH-X). Methylene carbon resonances typically have chemical shift ranges from 20 to 40 ppm, while a methine carbon with an attached oxygen has a chemical shift of 60–75 ppm. Consequently, establishing that the HSQC spectrum of an isolated metabolite is minus one methylene resonance that was observed in the parent molecule and has a new methine resonance with a chemical shift between 60 and 75 ppm can be key in the structural assignment of a metabolite that has undergone an aliphatic oxidation.

Multiple bond correlation experiments provide correlation between ^1H and an X nucleus (either ^{13}C or ^{15}N) that are two, three, and sometimes four bonds removed. As with the one bond experiments, there are several varieties of multiple bond experiments. The HMBC, a ^1H detected experiment, is the most sensitive. Data from all these types of experiments enable the assignment of ^{13}C chemical shift to quaternary carbons. Additionally, these experiments provide data that “skips over” heteroatoms to provide correlation between isolated spin systems. One example of the utility of this experiment is defining the location of GSH addition. Cross peaks from the methylene resonance of the GSH cysteine through the sulfur to a carbon resonance on the parent

molecule can definitively establish the site of conjugation [138]. Beyond this, in conjunction with the HMQC/HSQC data, the HMBC data enable the assignment of ^{13}C chemical shifts which in turn establishes the carbon backbone of the molecule. This is particularly advantageous when the structure of a metabolite is beyond the expected biotransformation.

5.4.4 Strategy for NMR Characterization of Metabolite Structure

Having reviewed the NMR-active nuclei, sample preparation, and common experiments, it is also appropriate to examine the overall strategy of how to use this information in assigning the structure of a metabolite. The first step is deciding if NMR data are needed. There are many situations where MS or MS/MS data are sufficient to unequivocally identify the chemical structure of a metabolite. For example, a parent molecule that has a single methoxy moiety and the MS data indicate a difference of 14 amu between the metabolite and the parent: in this situation, NMR analysis would not typically be necessary. Once it is decided that NMR analysis is required, the type of NMR data that are needed should be considered. This will factor into the decision about the amount of material needed for analysis. Can the structure of the metabolite be determined with 1D ^1H NMR? This is often a function of the complexity of the parent molecule. Molecules with multiple aromatic systems and redundant functional groups will likely require more complex experimentation to provide an unambiguous structural assignment.

If it is suspected that 1D ^1H analysis would be sufficient, would it be easier to isolate the material or pursue LC-NMR? If 1D ^1H analysis is not going to provide the answer, can a COSY or TOCSY experiment suffice? Often, in molecules with rich ^1H spin systems (e.g., steroids), 2D ^1H - ^1H data can provide adequate insight for definitive structural characterization even in molecules with complex spin systems. In circumstances where there is novel or unprecedented metabolism suspected, a full suite of 1D $^1\text{H}/^{13}\text{C}$ and 2D data may be required. It is a situation like this where the interplay between the COSY, HSQC, and HMBC data is critical. All these data must support the assignment of the metabolite structure. Once the ^1H chemical shifts are assigned and the carbon backbone of the metabolite is established, stereochemistry may be considered. For these situations, nOe or NOESY experiments may have to be explored.

In any of the scenarios described above, two things are absolutely required before the NMR analysis of a metabolite. First, a comprehensive analysis of the parent molecule should be performed where all ^1H and ^{13}C resonances are carefully assigned. The complete assignment of the parent makes the structural assignment of the metabolite a much easier process. Secondly, all other data, spectroscopic, chromatographic, and biological, should be incorporated into the assignment of a metabolites structure. The melding of all this information should paint a complete picture.

5.4.5 HPLC-NMR

Since its inception over 30 years ago, the coupling of liquid chromatography and NMR instrumentation has grown to become a common laboratory technique within the pharmaceutical industry. Much of the early LC-NMR work paralleled LC-MS using “on flow” techniques to interface the two instruments, in which NMR data

was collected in real time as the chromatographic system is constantly flowing. This work lacked sufficient sensitivity for routine practical application in drug metabolism studies and eliminated the possibility of two dimensional experiments. Since that time, several strategies have been developed to resolve these issues and are discussed in detail below. Proponents of LC-NMR claim the advantage of eliminating the step of a separate chromatographic isolation. However, the advantages of directly coupling NMR and HPLC instrumentation must be considered against compromises in performance made to each technique to achieve a hyphenated system. In LC-NMR, chromatographic fidelity is often compromised because the NMR cell volume is typically large (100 μL or greater) when compared to the cell volume of other detectors (UV 10 μL or less). Additionally, the presence of two large residual solvent lines from the mobile phase in the ^1H NMR spectrum can mask structurally informative analyte resonances. Despite these challenges, LC-NMR has proved to be a popular technique for the structure elucidation of metabolites.

Three common approaches to the acquisition of LC-NMR data are on-flow, stop-flow, and peak storage. Early LC-NMR experiments used direct acquisition of NMR data during chromatographic separation. These on-flow techniques were conceptually simple and required minimal hardware development. However, they were limited by the small number of scans that could be collected over a chromatographic peak as it elutes through the NMR flow cell. Each scan has a fixed duration, typically 2–3 s. If a given chromatographic peak is 30–60 s wide, this only allows 10–30 scans per peak. In the case of metabolites, this is generally insufficient time to collect data with adequate signal to noise for confident interpretation. To address this issue, several techniques have been designed to automatically isolate the peak of interest from the flow stream and direct it to the NMR flow cell where acquisition of data can be performed for extended periods of time. This enables one-dimensional spectra to be acquired with greater signal to noise and potential acquisition of two-dimensional spectra. One commonly used approach is stop-flow, where the chromatographic peak of interest is centered in the NMR flow cell by halting the flow of mobile phase [139]. Once the NMR data is acquired, flow is resumed. While this approach allows for the collection of a greater number of scans, it adversely affects the chromatographic separation of later eluting analytes. A second challenge with this approach is chromatographic fidelity. As stated above, the relatively large volume of the NMR flow cell can decrease the resolution of two closely eluting peaks. This problem is accentuated if the peak of interest is preceded by a peak of much greater abundance, as is common with metabolites and parent compounds. Another common approach is loop storage, where the chromatographic peaks are channeled from the mobile phase flow to storage loops and later pumped into the NMR cell after the chromatographic analysis is completed [140]. This technique allows analysis of multiple components of interest from a single chromatogram, while retaining chromatographic fidelity. However, loop storage may reduce NMR sensitivity because of postcolumn band broadening. The band broadening is the result of additional post column dead volume caused by extra valves and capillaries required to divert the chromatographic peaks. Obviously, the degree of loss in sensitivity will be variable and depend on the system configuration.

A variation on the loop collection strategy is in-line LC-SPE-NMR. LC-SPE-NMR adds an additional automated in-line sample handling step, which traps the chromatographic peak on a SPE cartridge [141]. In this method, the chromatographic eluent is diluted with aqueous mobile phase after the analytical separation to make the solvent

system less retentive. The mobile phase is then channeled to an SPE cartridge when a peak of interest is detected. Because of the now lower elutrophic strength of the mobile phase, the peak is trapped onto the cartridge. The cartridge is dried and the analyte subsequently eluted in a much smaller amount of deuterated solvent (typically deuterated acetonitrile). This procedure significantly increases the concentration of the analyte in the NMR cell and hence sensitivity of the overall system. Additionally, because the chromatographic peak is eluted with a single solvent, it reduces the need for solvent suppression as well as helps maintain maximal chromatographic fidelity. The primary disadvantage of the technique is the need to customize each analysis with the appropriate trapping cartridges and solvent conditions to achieve efficient retention and release of analyte.

5.5 QUANTITATIVE ASPECTS

As described above, the identification of metabolites is important in drug research. Additionally, in many cases, it is also important to determine the concentrations of metabolites in *in vivo* and *in vitro* samples. The degree of accuracy needed in quantitating metabolites can differ with the question being addressed and the stage in research/development. Some questions require high accuracy (e.g., measurement of pharmacologically active metabolites and comparison of metabolite exposures across species), while other questions can be adequately addressed with less precise estimates (e.g., estimates of the contribution of a major route of metabolism and which metabolites appear to be predominant in the profile in circulation). The selection of the quantitation method is driven by a balance of the need and the resources required. The use of synthetic standards of metabolites and standard bioanalytical methods is done when precise measurements are needed and is beyond the scope of this section. However, determination of metabolite concentrations in which authentic synthetic standards can also be done using radiometric approaches and NMR spectroscopy, and these approaches are described below.

5.5.1 Radiometric Quantitation

Radiometric quantitation of metabolites offers the advantage that authentic standards of metabolites are not required in order to quantitate them. Since the radioactivity response is strictly determined by the number of radioactive atoms within the molecule, and not dependent on spectral properties of the molecule, metabolite and parent responses will be equivalent to each other. (This is of course provided that the radionuclide is not lost on metabolism. A judicious selection of the position of incorporation of the radioactive atom within the parent drug molecule is essential to avoid loss of the atom through metabolism.)

Radiometric quantitation requires the resolution of metabolites by HPLC. A small portion of effluent is split to go to the mass spectrometer and the remaining large portion is diverted for radiometric detection. The disproportionate split is necessary because MS detection is vastly more sensitive than radiometric detection of carbon-14 or tritium. The effluent can be radiometrically quantitated by three methods (in order of sensitivity): flow detection, stop-flow detection, and off-line quantitation of collected fractions.

In radiometric flow detection, the HPLC effluent is diverted to a flow detector into which a liquid scintillation fluid is pumped, typically at a ratio of 2:1 to 4:1. The scintillations are detected in a flow cell, the volume of which determines the sensitivity and the resolution of the peaks. Large flow cells will increase sensitivity because the residence time of the radioactive peak within the cell is greater, but there is a greater chance that closely eluting metabolites will lose baseline resolution. Small cells will do the opposite. Flow cell volumes are usually around one-fifth to one-tenth of the volume compared to the total flow rate per minute (e.g., for a 1 mL/min HPLC flow and 3:1 ratio of scintillant, a flow cell of 0.5 mL would be appropriate). The total amount of radioactivity injected onto the column and the number of radioactive peaks is very important for radiometric flow detection. In general, injection of 10,000–20,000 dpm represents a lower limit, unless there are very few metabolite peaks. However, injection of too much radioactivity can cause a loss of resolution of peaks. In some instances, determining the correct amount to inject on column needs to be optimized experimentally to obtain data suitable for quantitation.

The sensitivity and signal-to-noise ratio of radiometric flow detection can be increased using stop-flow techniques. The technology for this has emerged over the past 10 years or so. It requires connectivity between the radiometric flow detector and the HPLC pumps such that when radioactivity in the detector exceeds a user-defined threshold, the detector will trigger the pumps to slow down or stop. The radioactive peak will stay in the detector cell for a long enough time to permit more accurate counting. When the accuracy of the reading has been attained, the pumps are reactivated and the flow restarts, until the next radioactive peak is detected. While this approach is suitable for accurate determinations of radiometric HPLC profiles, it can lengthen the total HPLC run time for a single injection to several hours. Thus, it is not suitable for real-time analysis needs such as optimization of chromatography or active, iterative analysis of mass spectral data.

Finally, radiometric detection can be done by collecting fractions from the HPLC and individually counting the samples with liquid scintillation counting. This is considerably more tedious and labor-intensive; however, it offers the most sensitive quantitation, and total radioactivity injections as low as 500 dpm can still yield good data. As with radiometric flow detectors, sensitivity is increased with larger fractions which causes decreases in resolution and vice versa. Fractions can be collected into standard liquid scintillation vials or using newer 24- and 96-well plates for scintillation counters that can measure radioactivity in plates. In the latter case, there are plates available in which the scintillant is embedded into the clear plastic on the plates such that scintillation fluid does not need to be added to the samples. Such fractions can be recovered for further spectral analysis as needed.

The greatest advantage offered by radiometric quantitation methods, as mentioned above, is the ability to provide quantitation of individual metabolites without requiring authentic standards of these metabolites for construction of calibration curves. It also offers the ability to readily identify where the drug-related materials elute in the HPLC in a highly complex array of materials in a biological matrix, which permits the analyst to thus focus on the mass spectral data coincident with these retention times. However, radiometric approaches have several distinct disadvantages which cause them to be generally reserved for use in later stages of drug research. First, a large initial investment is needed to carry out the custom radiosynthesis of new compounds, with the label in an acceptable, metabolically inert position. There are additional costs

involved in the maintenance of a laboratory in which radioactivity is used (registration with government nuclear regulatory authorities, extensive training of personnel, careful management of inventories, security issues, and costs of proper disposal of radioactive wastes).

Finally, a technique for measuring carbon-14 that has recently emerged for use in quantitatively measuring metabolite profiles is accelerator mass spectrometry (AMS). While this technique also uses carbon-14, it is important to note that it is not radioactive decay that is being measured, but rather it is carbon-14 atoms themselves. Thus, this method is far more sensitive and can permit the use of carbon-14 at levels of 1000-fold less than when using radiometric measurements. Such sensitivity can offer an option for conducting quantitative metabolism studies in special circumstances where a typical radioactive dose may not be able to be given to human study subjects (i.e., when estimations of tissue dosimetry exceed allowable limits). Because doses of carbon-14 can be extremely low, the AMS approach can be applied in human carbon-14 metabolism studies without requiring prerequisite animal carbon-14 studies and therefore could be done earlier in clinical development. The technique suffers the disadvantages of requiring off-line analysis of HPLC effluents as well as expensive and sophisticated instrumentation. Nevertheless, it is reasonable to expect that this technology will increase in use in the future.

Radiometric quantitation can also be used as a bridging method to MS quantitation. In this approach, a biological sample generated using radiolabeled parent drug is used as the mother stock of a metabolite(s). The biological sample will be analyzed using HPLC with radiometric detection, and using the specific activity of the parent compound, the total concentration of drug-related material in the sample, the percentage which is comprised by a metabolite of interest, and the concentration of the metabolite in this biological sample can be calculated. Then, the MS response for this metabolite can be calibrated using this concentration value. Thus, samples containing unknown concentrations of the metabolite can be measured using the biological sample of known concentration in the construction of standard curves [142].

5.5.2 Quantitation Using NMR Spectroscopy

In the absence of a synthetic standard of a metabolite, and in the absence of a radiolabeled standard of the parent drug, NMR spectroscopy can be used as a quantitative tool for metabolites [143,144]. A critical step in the definitive structural characterization of a metabolite is its isolation for NMR analysis. As stated earlier, isolated samples for NMR analysis can have concentrations of approximately 0.5 mM (~40 µg of isolated material). The material isolated for NMR experiments could also easily be utilized as a quantitative standard for assessment of metabolite concentration if the concentration of the NMR solution were determined. However, the microgram-level mass of the isolated material precludes gravimetric analysis. Quantitative NMR can fill this void.

Unlike many other spectroscopies, NMR response is independent of the structural characteristic of the molecular moiety. A resonance from single hydrogen in a 0.1 M carbohydrate solution will have the same response as single hydrogen from a 0.1 M solution of a steroid, provided the data are acquired appropriately. This enables the calibration of NMR systems to provide quantitative information without authentic standards.

Like other quantitative systems, quantitative nuclear magnetic resonance (qNMR) requires the calibration of the acquired signal against a known standard. This is performed either through the use of an internal standard that is added to the isolated sample or by the calibration of an external signal that is electronically or mathematically added to the sample's NMR signal. In the first case, the internal standard may be added as a separate chemical entity or the signal from the residual deuterated solvent used. In either situation, the internal reference signal must be free from interference, stable, and nonvolatile. It is surprising how limiting these few simple restrictions can be.

In an effort to surmount these restrictions, an electronic referencing method was developed [(electronic reference to access *in vivo* concentrations (ERETIC))] [145]. Conceptually, this method places an artificial signal in the data of a 1D ^1H NMR spectrum as it is being acquired. Because of the synthetic nature of the signal, this method has the advantage of being able to control both the frequency and the magnitude based on the needs of the sample. However, in order to produce this artificial signal, specialized hardware and pulse sequences are needed for the acquisition of ERETIC data.

An alternative to ERETIC is the arithmetic merging of an artificially generated NMR signal with the NMR signal of a metabolite [artificial signal incorporation for calculation of concentration observed (aSICCO)] [146,147]. In this method, a mathematically generated FID is merged with a standard of known concentration. This allows the calculation of the "concentration" of the aSICCO signal. In turn, if the aSICCO signal is merged with the acquired NMR signal of a metabolite, the concentration of the metabolite can be calculated. In all the methods described above, the concentration of the isolated metabolite can be determined with precision and accuracy of $\pm 10\%$.

5.6 CONCLUSIONS

Metabolite structure elucidation represents an important activity in the design of new drugs as well as a required activity in the characterization of drug candidates during the development process. The identification of drug metabolites is a complex process that utilizes several types of sophisticated high technology instruments. However, the successful employment of these tools and technologies requires scientists knowledgeable of xenobiotic metabolism, the types of reactions that molecules can undergo in the body, the drug-metabolizing enzymes, as well as insight into fundamental organic chemical reactions. Furthermore, the strategy regarding when metabolite identification is needed to address questions regarding the dispositional, pharmacological, and toxicological aspects of drugs remains the domain of the individual scientists engaged in the discovery and development of new drugs.

6.1 BIOACTIVATION AND OXIDATIVE STRESS SUMMARY

Drug metabolism generally renders drug molecules less reactive and increases their hydrophilicity, assisting the drug, and its metabolites' elimination from the body. Drug metabolism can also uncover more pharmacologically reactive groups, thereby making the metabolite more reactive than the parent compound (prodrug). Reactive metabolites (RMs) can also be created by the metabolism of certain drugs. RMs are generally short lived and are *bioinactivated* by conjugation reactions with glutathione (GSH). If cellular stores of GSH become depleted or its production has been impaired, RMs, created by this bioactivation of the parent compound, can covalently bind with cellular macromolecules and/or induce oxidative stress, which are important initiators of toxicity.

The propensity of a drug molecule to be bioactivated is a function of its chemistry. A number of functional groups have been identified that are frequently associated with bioactivation and subsequent drug-induced toxicity (Table 6.1). In some instances, these structural fragments are crucial to the potency and pharmacological selectivity of the compound. However, the mere presence of these moieties in a drug or compound

TABLE 6.1 Examples of Drugs Causing Off-target Clinical Adverse Drug Reactions and the Reactive Intermediates Involved

Drug	Adverse Reaction	RM
Amodiaquine	Hepatotoxicity	Quinone imine
Paracetamol	Hepatotoxicity	Quinone Imine
Halothane	Hepatotoxicity	Acyl halide
Diclofenac	Hepatotoxicity	Quinone imine/acyl glucuronide
Tacrine	Hepatotoxicity	Quinone methide
Indomethacin	Hepatotoxicity	Quinone imine/chloro-indole
Valproic acid	Hepatotoxicity	α , β -Unsaturated carbonyl
Vesnarinone	Hepatotoxicity	Iminium ion
Phenacetin	Hepatotoxicity	Quinone imine
Phenytoin	Teratogenicity/hepatotoxicity	Free radical
Clozapine	Agranulocytosis	Nitrenium ion
Aminopyrene	Agranulocytosis	iminium
Ticlopidine	Agranulocytosis	S-oxide
Sulfamethoxazole	Toxic epidermal necrolysis	Hydroxylamine/nitroso
Lamotrigine	Toxic epidermal necrolysis	epoxide
Carbamazepine	Hypersensitivity	Quinone imine/epoxide
Tienilic acid	Hypersensitivity	S-oxide
Felbamate	Aplastic anemia	Atropaldehyde
Remoxipride	Aplastic anemia	Hydroquinone

does not automatically result in bioactivation and toxicity [1]. A combinatory effect of a number of other factors will ultimately determine whether a RM will be either detoxified and eliminated or cause toxicity. Dose and duration of therapy of a drug will control the levels of exposure to the drug a patient receives; genetic factors may also affect rates of RM formation, cellular defense mechanisms, and susceptibility to immune-mediated toxicities; and environmental factors and disease state of a patient can influence their ability to detoxify and/or eliminate RMs.

This chapter is focused on the role of drug metabolism and bioactivation in oxidative stress and adverse drug reactions (ADRs). These main themes are discussed in a general manner and then further explored, as case studies, to demonstrate these principles.

6.2 DRUG METABOLISM AND BIOACTIVATION

Drug metabolism and bioactivation are catalyzed by a range of enzymes that occur naturally in the body and have endogenous substrates. Metabolism is divided into two phases. Phase I involves the functionalization of the drug; functional groups are added or revealed, thereby making the metabolite more water soluble and available for conjugation (phase II metabolism). Phase II metabolism involves conjugation of the phase I metabolite, at the functional groups, rendering them less reactive and more easily eliminated.

6.2.1 Involvement of Cytochrome P450 Enzymes in Bioactivation

The cytochrome P450 (CYP) superfamily of enzymes is responsible for the majority of phase I metabolism and is, therefore, responsible for the majority of RM formation

[2,3]. Within this enzyme superfamily exist a number of isoforms that differ in substrate specificity. Expression of different CYP isoforms varies between species, sex, and individual and can be altered through environmental changes, diet, and disease state [4]. Each organ, in a single individual, will have a different complement of CYP isoforms, making them differentially susceptible to drug-induced toxicity [2]. The CYP enzymes are found predominantly in the liver and most drug biotransformation occurs here, making the liver a frequent target of drug-induced toxicity [5].

Quantitatively, the CYP isoforms in the endoplasmic reticulum are the most important group of enzymes involved in this process. However, products of phase II metabolism can also lead to toxicity [6]. Additionally, non-CYP oxidative enzymes, such as myeloperoxidase and prostaglandin H synthetase, have been implicated in the bioactivation of drugs and other chemicals [7], the metabolites of which are thought to be responsible for observed toxicity, for example, clozapine and agranulocytosis, benzene, and aplastic anemia [8–11].

6.3 REACTIVE METABOLITES OF DRUG MOLECULES AND INITIATION OF TOXICITY

The concept that small organic molecules can undergo bioactivation to electrophiles and free radicals, and elicit toxicity by covalent modification of cellular macromolecules, has its basis in chemical carcinogenicity and the pioneering work of the Millers [12,13], who studied the hepatotoxic effects of *p*-dimethylaminoazobenzene in the rat and found that aminoazo dyes become tightly bound to the protein constituents of liver tissue. The application of such concepts to human drug-induced hepatotoxicity was established through the studies of Brodie, Gillette, and Mitchell on the covalent binding to hepatic proteins of toxic doses (samples were obtained from overdose patients) of the widely used analgesic acetaminophen (APAP) [14,15].

6.3.1 Chemical Nature of Reactive Drug Metabolites

RMs may be broadly classified as either electrophiles or free radicals [16]. In the vast majority of cases, the ultimate reactive species is electrophilic in nature [1], for example, epoxides and quinones. Electrophiles are reactive because they are electron deficient and have either a high positive charge density (hard electrophiles) or a low positive charge density (soft electrophiles) at the electrophilic center [17]. RMs that possess unpaired electrons can be described as free radicals. Free radicals usually abstract a hydrogen atom from other molecules rather than becoming covalently bound; however, they can also add to double bonds [6]. Free radical reactions can be self-propagating: abstraction of a hydrogen atom from a lipid can initiate a chain reaction leading to lipid peroxidation, oxidative stress, or modification of other types of biological molecules by free radicals [7].

6.3.2 Mechanisms Underlying Drug-Induced Toxicity

RMs have the ability to interact with cellular proteins, lipids, and nucleic acids, leading to protein dysfunction, lipid peroxidation, DNA damage, and oxidative stress (Fig. 6.1)

Figure 6.1 Relationship between drug metabolism and toxicity. Toxicity may accrue through accumulation of parent drug or, via metabolic activation, through the formation of a chemically reactive metabolite, which, if not detoxified, can effect covalent modification of biological macromolecules. The identity of the target macromolecule and the functional consequence of its modification will dictate the resulting toxicological response [18]. (See color insert.)

[18]. Additionally, the metabolites may induce disruption of ionic gradients and intracellular calcium stores, resulting in mitochondrial dysfunction and loss of energy production. This impairment of cellular function can result in cell death and possible liver failure [18].

6.4 ADVERSE DRUG REACTIONS

ADRs are defined as a response to a drug that is noxious, unintended, or undesired occurring at doses normally used for the prevention, diagnosis, or treatment of disease [19]. Despite intensive investigation in the fields of chemical toxicology and molecular biology, ADRs remain a major complication of drug therapy [20,21]. ADRs account for a significant number of hospital admissions each year and contribute to patient morbidity and mortality [21]. A pilot study investigating hospital in-patient ADR development found that 19% of patients suffered an ADR, the majority of which were avoidable [22]. In addition, ADRs represent a major issue for pharmaceutical industries, accounting for 30% of compound attrition during the drug development process [23]. Drug toxicity can mimic natural disease and almost any body system can be adversely affected by drugs [24].

6.4.1 Classification of Adverse Drug Reactions

ADRs can be classified as “on-target” or “off-target/idiosyncratic” reactions [25–27]. On-target reactions can be predicted from the known primary or secondary pharmacology of the drug and often represent an exaggeration of the pharmacological effect of the drug. They show simple and clear dose–response relationships and, therefore, can usually be avoided by dose reduction and are only rarely life threatening [26]. In contrast, idiosyncratic adverse reactions cannot be predicted from knowledge of the basic pharmacology of the drug. They are extremely host-dependent and uncommon reactions [28].

Drug–drug interactions can influence both pharmacodynamic (PD) and pharmacokinetic (PK) properties of coadministered drugs. An understanding of the role of DDIs in on-target toxicity requires an understanding of PKPD properties of all coadministered agents. Pharmacodynamic interactions can produce synergistic and additive effects, leading to toxicology. For example, consumption of alcohol while taking antihistamines causing drowsiness can lead to impaired psychomotor skills [29]. PK interactions influence concentration of drug by alteration in absorption, distribution, metabolism, and elimination of one agent by another. Coadministration of a drug with an agent that inhibits its clearance mechanisms leads to an increase in plasma levels, potentially hitting a toxic threshold. The anticoagulant warfarin is metabolized by CYP enzymes in the liver, specifically CYP2C9 and CYP3A4. Therefore, agents that inhibit either of these two enzymes, such as fluconazole [30], will lead to an increase in prothrombin time and possible bleeding.

6.4.2 Idiosyncratic Adverse Drug Reactions

Idiosyncratic drug reactions represent a major problem for the pharmaceutical industry because they add significant uncertainty to the process of drug development and can ultimately lead to drug withdrawal or warnings in drug labeling [31,32]. They are particularly difficult to deal with because they are likely to be discovered late in development or after the drug has been approved; this has important implications as the latter a drug fails, the more expensive is the failure [33,34]. Drug attrition rates are at their highest; the overall success rate for approval of a new chemical entity (NCE) is 11% and with 62% of attrition occurring at phase II clinical trials, the financial cost is huge [32]. During 1975–2000, over 10% of newly approved drugs in the United States were withdrawn or given black-box warnings [31]. In 1991, adverse PK and bioavailability results contributed to a total of 40% of attrition. In 2000, this had been reduced to 10%, but lack of efficacy and safety each contribute to 30% of drug attrition [32].

The exact mechanisms of idiosyncratic drug reactions are still unclear; however, it is believed that some idiosyncratic reactions are initiated by RM [28,35], which bind covalently to macromolecules and either cause direct cell damage or trigger an immune response leading to cell death [34,36,37]. Therefore, the propensity of a NCE to undergo bioactivation needs to be determined at an early stage of the drug development process. Considerable efforts have been made to develop screening systems for RM based on subcellular liver fractions [38,39] or isolated hepatocytes [39]. However, a noninvasive, generic, and quantitative method for assessing bioactivation of drugs in experimental animals, human volunteers, and patients is not currently available.

6.5 ADVERSE DRUG REACTIONS, BIOACTIVATION, AND OXIDATIVE STRESS

It is a widely accepted hypothesis that some idiosyncratic reactions are initiated by RM [28,35], which bind covalently to macromolecules and either cause direct cell damage or trigger an immune response leading to cell death [34,36,37]. Metabolic activation of drug molecules to electrophilic RM can contribute to stress in the cell and interfere with normal cellular homeostasis. Drug-induced oxidative stress can be defined as an imbalance between prooxidants and antioxidants in a cell caused by either parent drug or a reactive intermediate of metabolism [40,41]. Oxidative stress is most commonly mediated by reactive oxygen species (ROS); these include the oxygen free radicals, superoxide anion ($O_2^{\cdot-}$), hydroxyl radical ($HO^{\cdot}$), and nonradical hydrogen peroxide (H_2O_2) [42]. Other species and processes that can mediate oxidative stress include reactive nitrogen species (RNS), RMs of xenobiotics, reduced transition metals, γ -radiation in the presence of oxygen, activated neutrophils, UV light, and by-products of lipid peroxidation [43]. Oxidative stress can lead to cell damage through a number of mechanisms including lipid peroxidation, protein oxidation, DNA oxidation, and mitochondrial damage [44]. Products of oxidative damage can also have prooxidative effects, thereby propagating oxidative damage in the cell [45].

6.5.1 Generation of Reactive Oxygen Species

ROS are generated, in small amounts, in the cell by normal physiological processes [46]. The mitochondria serves as a source of ROS through the electron transport chain, which has redox centers that can leak electrons to molecular oxygen generating $O_2^{\cdot-}$ [47–49]. Peroxisomes contain high amounts of H_2O_2 that can leak out into the cytosol if degradation via catalase is inefficient [50–52]. A number of enzymatic processes can increase the amount of oxidants in the cell, including the CYP monooxygenase system [53]. This enzyme system oxidizes xenobiotics in phase I metabolism; however, incomplete oxidation of a substrate can lead to reduction of O_2 [54]. Electrons can also escape from flavins in the NADPH/P450 reductase enzyme [55]. The cell has an extensive antioxidant defense system that is put into play when an imbalance in pro- and antioxidant species is detected [41,56,57]. These systems can degrade ROS, provide ROS scavengers, prevent/repair oxidation of lipids, and maintain the thiol status of the cell [44].

6.5.2 Cellular Defense against Drug-Induced Oxidative Stress

Once cellular stress has been detected, the cell can activate an immediate adaptive defense response via the upregulation of gene expression that is mediated by transcription factors such as activator protein-1 (AP-1) [58], nuclear factor κ B (NF κ B) [59], and nuclear factor erythroid-2 p45-related factor 2 (Nrf2) [60,61]. These are regulatory proteins that often reside in the cytoplasm and translocate to the nucleus on activation where they bind to specific DNA sequences or response elements within gene promoter regions. They can then recruit RNA polymerase and other binding proteins to initiate gene transcription [62]. Activation and translocation of a transcription factor is often oxidant and thiol status sensitive. GSH synthesis is highly inducible on conditions of oxidative stress and GSH depletion. Transcription factor controlling the expression of

enzymes involved in GSH synthesis can be directly activated by electrophilic species that conjugate to GSH depletion as a positive feedback mechanism of the adaptive response [63,64].

Although oxidative stress alone is not enough to kill a cell, all, the ability of RM to bind to cellular macromolecules, initiate oxidative stress, and promote GSH depletion, contribute to damage to key intracellular organelles and can subsequently lead to cell death.

6.5.3 The Role of Glutathione in Cellular Defense

GSH is a tripeptide, derived from the amino acids cysteine, glutamate, and glycine. It is a major endogenous antioxidant within hepatocytes owing to its free thiol group and its relatively high abundance (~ 10 mM in hepatocytes). It is present in two forms: reduced (GSH) and oxidized (GSSG). The change in the ratio between the two forms is directly reflective of intracellular redox alterations [65]. GSH homeostasis within hepatocytes is maintained through GSH synthesis and utilization. Synthesis occurs in the cytosol through a two-step ATP consuming reaction. The first step comprises the synthesis of γ -glutamylcysteine. This occurs through the condensation of cysteine and glutamate, catalyzed by γ -glutamylcysteinyl ligase. GSH synthetase then further catalyzes the formation of GSH from γ -glutamylcysteine and glycine [66,67]. It is then used either as an enzyme cosubstrate or as a scavenger molecule in the presence of an oxidized substrate, resulting in the formation of GSSG. Under normal physiological conditions, GSSG can then be recycled back to GSH by the enzyme GSH reductase (Fig. 6.2) [67].

GSH is critical for cellular function and cell survival, playing a major determinant of redox potential. The antioxidant role of GSH is to quench endogenous oxidative species and to overcome exogenous oxidative stress. Increased levels of ROS occur as a result of infection, inflammation, xenobiotics, and intracellular stress. This is potentially hazardous for the cell as ROS can oxidize proteins, lipids, and DNA, causing oxidative damage. GSH also acts as a hydrogen donor for GSH peroxidase. This enzyme is responsible for the subsequent conversion of H_2O_2 to water in parallel with catalase. The level of GSH consequently has a direct impact on the function of GSH peroxidase. GSH peroxidase also plays a role in the repair of lipid peroxidation. Additionally, GSH acts as a scavenger of RNS such as peroxynitrite ($ONOO^-$). An imbalance of endogenous oxidants and antioxidants could result in oxidative stress, emphasizing the crucial role GSH plays in cellular defense. Furthermore, GSH can act as a cofactor substrate in conjugation reactions of xenobiotics under the catalysis of GSH transferases. This acts as a detoxifying mechanism enabling the exportation of drugs and xenobiotics through the multidrug-resistance-associated transporter family [67]. As GSH plays a fundamental role in cellular defense, perturbation of cellular levels can lead to oxidative stress and/or potential irreversible binding of RMs to cellular macromolecules, resulting in direct cell toxicity or an immunological reaction.

6.5.4 Reactive Metabolites and Mechanisms and Consequences of Oxidative Stress

The formation of RM through bioactivation of drug molecules can push the balance toward a more oxidative environment in the cell by stimulating overproduction of ROS,

Figure 6.2 Enzyme regulation of GSH synthesis and recycling pathway. GSH is synthesized by a two-step ATP-dependent pathway. γ -Glutamylcysteine is formed from L-glutamate and cysteine, which is catalyzed by Glutamylcysteine ligase γ -GCL (1). Glycine is then added at the C-terminal of γ -glutamylcysteine through the catalysis of GSH synthetase (2). Redox cycling between GSH and GSSG is mediated by GSH reductase and GSH peroxidase [68]. *Source:* Adapted from DeLeve *et al.*, 1991.

introduction of electrophilic species, and disruption of thiol status. Some mechanisms by which ROS and other prooxidant species can be generated and how they cause oxidative damage to cellular organelles and macromolecules are outlined below; often, these mechanisms propagate and amplify the oxidative insult.

6.5.4.1 Redox Cycling of Drug Metabolites and Their Role in ROS Generation.

RM of xenobiotics can increase ROS by redox cycling, as in the classic case of paraquat [69,70]. Oxidative stress arises when the xenobiotic is reduced by reductases to a semiquinone radical that reduces molecular oxygen to superoxide radicals and reforms the drug or metabolite; repeated reduction and oxidation of a xenobiotic can generate cytotoxic levels of hydrogen peroxide and GSSG [44,71]. Structures capable of redox cycling include catechols and other quinone compounds, iron chelates, and aromatic nitro compounds [72]. Iron chelators, administered in cases of iron overload following blood transfusion, are associated with redox-cycling-mediated toxicity [73]. Drug-induced redox cycling is often associated with quinone moieties in the drug molecules. Cytotoxicity of quinones has been attributed to free radical generation and to arylation of cellular nucleophiles. For redox-cycling quinones, cell injury is associated with mitochondrial permeability transition, whereas aryating quinones directly depolarize the mitochondrial membrane and deplete ATP [74]. The quinone containing anticancer agent doxorubicin (Adriamycin) induced a dose-limiting cardiotoxicity by

inducing reactive species in the heart via redox cycling of the drug at complex I of the electron transport chain [75]. Diclofenac (DCF) quinone-imine-related redox cycling has been implicated in DCF-induced hepatotoxicity [76]. Redox cycling can instigate lipid peroxidation through the generation of ROS.

6.5.4.2 Role of Lipid Peroxidation in Generation and Propagation of ROS and Involvement in Cellular Damage. RM can initiate lipid peroxidation either directly if the RM is electrophilic or indirectly by increasing the generation of free radicals [16,77]. Lipid peroxidation can damage biological membranes [78], leading to further damage to the cell through increased permeability of the plasma membrane or the membranes of organelles [79]. Hepatotoxic mechanisms of carbon tetrachloride are thought to be mediated through lipid peroxidation and disruption of cellular homeostasis, which can lead to disruption of the cytoskeleton, cell signaling, and gene expression pathways [80,81]. Incubation of paraquat with liver microsomes or a system containing NADPH-cytochrome *c* reductase, NADPH, and microsomal lipid greatly increases the formation of malonaldehyde; the amount of malonaldehyde formed in these studies was dependent on the concentration of paraquat in the incubation mixture [82,83]. Oxidative stress has been implicated in the hepatotoxicity associated with the aromatic antiepileptic drugs, carbamazepine, phenytoin, and phenobarbital, as their metabolites increased malondialdehyde levels, oxidation of cardiolipin, oxidation of sulfhydryl proteins, and alteration of the cellular redox status [84].

6.5.4.3 Mitochondrial Dysfunction as a Consequence of Drug-induced Oxidative Stress. Products of lipid peroxidation, ROS, and electrophilic RMs can disrupt mitochondrial function through membrane damage, uncoupling oxidative phosphorylation [85,86] and critical protein oxidation [87], leading to depletion of cellular ATP levels that could ultimately lead to apoptosis and necrosis [49]. The anti-HIV drug class of nucleoside reverse transcriptase inhibitors (NRTIs), used to inhibit viral replication in host cells, induces a variety of serious ADRs including lactic acidosis and cardio and skeletal myopathies [88]. These prodrugs are phosphorylated into the active state and are believed to induce ADR through mitochondrial dysfunction and altered mitochondrial DNA [88]. Nefazodone is an antidepressant that was withdrawn from the market in 2004 owing to severe cases of hepatotoxicity resulting in 1 case of liver failure resulting in death or transplant per 250,000–300,000 patient years. The effect of nefazodone on the mitochondria and resulting hepatotoxicity has been investigated in isolated oxidative phosphorylation (OXPHOS) complexes, HepG2 cells, and sandwich human hepatocytes [89], in which it has been demonstrated that in isolated OXPHOS complexes nefazodone inhibits complex I.

6.5.4.4 Glutathione and Thiol Status Disruption in Drug-Induced Oxidative Stress. As discussed previously, drug metabolites are generally electrophilic species and can form GSH conjugates either enzymatically or nonenzymatically [90]. During alular GSH depletion, such as that seen during high RM exposure, other thiol groups, especially those on critical proteins, can become adducted or vulnerable to oxidation, cross-linking, and formation of mixed disulfides. APAP provides a good example of how thiol status is critical for the successful handling of electrophilic drug intermediates (Section 6.7.1).

6.5.4.5 Irreversible Binding of Reactive Metabolites to Cellular Macromolecules.

RMs usually have a low electron density (electrophilic) and as a result are capable of reacting with nucleophiles, molecular centers of high electron density. Nucleophilic targets are dependent on whether the electrophile is chemically defined as hard or soft. Hard electrophiles tend to react with nucleophilic N, O, and C in biological molecules. Hard electrophiles are likely to be genotoxic as they have the potential to react with DNA, forming DNA adducts [91]. This acts as the initiatory stage of carcinogenesis when the mechanism is genotoxic. Aflatoxin B₁ is a genotoxic carcinogen, which is bioactivated to 8,9 epoxide metabolite, which is then able to bind to DNA, forming B₁-N₇-guanine adducts [92,93]. This emphasizes both the importance of drug bioactivation and covalent binding in aflatoxin B₁ causation of drug-induced liver injury (DILI).

Soft electrophiles react more readily with sulfur and target cellular protein. Target proteins for adduction usually contain strong nucleophilic sites such as cysteine thiols, lysine amines, histidine imidazoles, and protein N-terminal amines [94–96]. As discussed previously, GSH plays a crucial role in protecting the thiol status of the cell by quenching endogenous oxidative species such as some drug RMs. However, in some cases, RM can overwhelm the GSH store and cellular GSH levels can become depleted, as in the case of APAP. The depletion of hepatic GSH has been shown to be an obligatory step to enable *N*-acetyl-*p*-benzoquinone imine (NAPQI) to covalently modify and potentially inhibit the function of a number of critical proteins within cells, leading to cell death and has been discussed previously [97]. A number of therapeutic drugs have been reported to undergo irreversible binding to various target proteins despite having different chemical structures and pharmacological actions. Metabolic bioactivation is usually a prerequisite, resulting in the formation of RMs, which are able to bind to proteins by nucleophilic substitution and/or Schiff base formation [98–100]. Irreversible binding with cellular protein has been well documented in retrospective association with drug toxicity, with a number of drugs incriminated, including APAP, amodiaquine, and clozapine [101–103]. However, protein adduct formation does not always lead to toxicity. This concept is best illustrated by APAP and its structural isomer 3'-hydroxyacetanilide (*N*-acetyl-*m*-aminophenol, 3-acetamidophenol; AMAP), where AMAP at the same molar dose as APAP was found to covalently bind to cellular protein and yet did not result in toxicity. The RM of APAP and AMAP, a quinone imine (NAPQI) and quinone, respectively, are chemically similar species, yet there is an intrinsic difference between them that accounts for the difference in ability to cause hepatotoxicity [104]. This introduced the concept of the critical protein hypothesis, delineating certain proteins as critical targets in hepatotoxicity [18,105]. Supporting this, the RM of APAP, NAPQI binds to a number of proteins. In mice, one of the major targets of NAPQI is urate oxidase, an enzyme lost during primate evolution. As a result, it is thought unlikely that irreversible binding to urate oxidase represents a role in APAP-induced hepatotoxicity in mice, as both humans and mice develop centrilobular necrosis with similar per kilogram doses [106]. This highlights the need to identify the critical protein adducts involved in the mechanism of DILI.

Drug-protein adducts can act as neoantigens and induce immune-mediated toxicity. Halothane is the best-studied drug with respect to immunoallergic hepatitis. A significant proportion of patients exposed to this inhalation anesthetic develop asymptomatic rises in transaminases. Fulminant irreversible hepatitis is a rare but life-threatening phenomenon. Most of the patients recorded in the literature with immunoallergic hepatitis had more than one exposure [107]. Antibodies have been detected in such patients

that recognize autoantigens and neoantigens created by trifluoroacetylation of hepatic proteins. Preincubation of halothane pretreated, but not control, rabbit hepatocytes with sera from patients with halothane-induced fulminant hepatic failure rendered the hepatocytes susceptible to the cytotoxic effects of normal lymphocytes *in vitro* [108]. This phenomenon was not observed in control hepatocytes. It is, thus, likely that drug-specific T cells may play a role in the pathogenesis of hepatocyte injury, but direct evidence for this lacks.

Halothane is metabolized by CYP2E1, such as APAP, but forms a chemically reactive acyl halide and bioactivation to the acyl halide is substantial as it is the only metabolic route available. It is hypothesized that the formation of the acyl halide triggers an immune response. Evidence for this concept of an immune trigger is both direct and indirect, with drug-specific antibodies showing that the drug has initiated an immune response in affected patients and newer metabolically inert inhaled anesthetics, such as enflurane and isoflurane, being rarely associated with hepatotoxicity (Fig. 6.3). Target proteins modified by the acyl halide have been identified with the principal chemical modification trifluoroacetylation of lysine residue [109–112]. Chemical modification of protein(s) is associated with the immune response observed with halothane hepatitis; however, there is no conclusive evidence that the antibodies mediate liver injury. Antidrug antibodies have also been observed with idiosyncratic drug

Figure 6.3 Metabolic bioactivation of inhaled anesthetics potential of new inhaled anesthetics to cause immune-mediated hepatotoxicity in man correlates with extent of metabolic bioactivation and liver protein adduct formation, which can be quantified experimentally (*in vivo/in vitro*).

TABLE 6.2 Idiosyncratic Drug Reactions with Evidence of Immune Involvement

Drug Class	Drug Name	Is There Evidence to Support Immune Involvement?
Anesthetic	Halothane	Yes
Analgesic	Diclofenac	Yes/no
	Sulindac	Yes
Antibiotic	Amoxicillin	Yes
	Erythromycins	Yes
	Minocycline	Yes
	Nitrofluantoin	Yes
	Rifampicin	Yes/no
Anticonvulsant	Phenytoin	Yes
	Phenothiazines	Yes
Antiepileptic	Carbamazepine	Yes/no
Antihypertensive	Dihydralazine	Yes
	Methyldopa	Yes
	Tienilic acid	Yes
Antithyroid	Propylthiouracil	Yes
Depression	Tricyclic antidepressants	Yes
Gout	Allopurinol	Yes
Hypertension	ACE inhibitors	Yes

Source: Amended from Ref. 115.

reactions to tienilic acid [113] and dihydralazine [114], but there is equivocal evidence that DILI such as that caused by halothane is immune mediated. Most of the information available is compatible with the hapten hypothesis where the drug undergoes bioactivation in hepatocytes leading to drug–protein conjugate formation in the liver. The current theory suggests that the occurrence of idiosyncratic drug hypersensitivity in man represents interplay between a number of factors, which include the chemistry of the drug, drug metabolism, and the immune system of the patient (Table 6.2). Whether cytokines may be useful biomarkers in such idiosyncratic cases is currently unknown, as is the mechanistic details. However, if the hapten hypothesis is correct it is clear that the inflammatory response induced by chemical insult such as APAP overdose compared to that of idiosyncratic DILI may be very different.

6.6 BIOMARKERS OF DRUG BIOACTIVATION

Clearly, drug metabolism can play an important initiating step in the development of ADRs, and RMs have been correlated with the toxicity of several drugs. Therefore, a major interest in biological and analytical techniques has been to minimize metabolic activation of drug candidates during the drug discovery process [1,116]. A variety of experimental approaches have been developed and applied to early optimization phases through to development stages of lead candidates. These studies are largely based on the discovery and quantitation of drug conjugates with endogenous molecules and *in vitro* trapping agents that serve as indicators of drug safety [117]. By allowing for

improved decision making, these indicators, referred to as *biomarkers*, can significantly improve the efficiency of drug discovery and development. However, these studies are time consuming and, in some cases, may delay the process of drug discovery without sufficient improvement in the safety of NCE.

Generally, chemically RMs are detected and estimated indirectly through the irreversible binding of uncharacterized radiolabeled material to hepatic protein [118] and/or the formation of stable metabolites such as GSH conjugates [119]. Until recently, most assays of RM formation *in vivo* and *in vitro* depended on measuring irreversible binding of radioactivity, using relatively laborious methods of exhaustive solvent extraction [118–120].

6.6.1 Trapping Agents and *In Vitro* Biomarkers of Bioactivation

Most RMs are electrophilic in nature because of the inherent reactivity and instability and can readily be trapped with a suitable nucleophile to form stable adducts; the strategy of trapping these intermediates *in vitro* is widely used [121,122]. The *in vitro* assay most widely used to screen for RMs is liver microsomes supplemented with a NADPH/NADPH regenerating system, as cofactor for CYP450-catalyzed reactions and a trapping agent [116,118]. Table 6.3 lists chemical traps that have been used in microsomal incubations for several reactive intermediates.

Methods of trapping RMs commonly include the use of GSH, GSH-ethyl ester, and *N*-acetyl cysteine (NAC), because of their nucleophilic nature they are able to conjugate spontaneously with electrophilic compounds. The most widely used trapping agent, GSH, contains a free sulfhydryl group, a soft nucleophile, that can react directly with soft electrophiles, including quinones, epoxides, nitrenium ions, alkyl halides, Michael acceptors, and so on to form stable GSH adducts [117,118]. GSH is present in a concentration of ~ 10 mM in the liver and can conjugate readily with metabolites with an electrophilic center, generated through the bioactivation by CYP450 enzymes. Hence, GSH serves as a natural trapping agent for chemically RMs and has been routinely used *in vitro* to screen and evaluate RM formation [119].

β -Mercaptoethanol has been successfully used to trap several RMs generated by microsomes and isolated enzymes. In most cases, where the structure of the intermediate can be deduced, the precursor of the β -mercaptoethanol adduct has been an α , β -unsaturated carbonyl [123], a quinone [124], or a quinone imine [124].

TABLE 6.3 Examples of Reactive Intermediates and Trapping Agents in Microsomal Incubation

Trapping Agents	Reactive Intermediate
GSH, GSH-ethyl ester, mercaptoethanol, cysteine, <i>N</i> -acetyl cysteine	Quinones, enones
GSH (ester), mercaptoethanol, cysteine	Thiophenes
Cyanide	Iminium ions
Semicarbazide, methoxylamine	Aldehydes, furans
Lysine	Imides, aryl halides
lysine + cysteine	Furan, epoxide
TEMPO	Free radical trap

GSH-ethyl ester has been used as a more lipophilic thiol [124] and was shown to increase the mass spectrometry (MS) sensitivity by ~10-fold for the detection of RMs [124]. Trapping of free radicals employs spin-trapped reagents, for example, electron paramagnetic resonance spectroscopy in the presence and absence of the spin trap, 5,5-dimethyl-1-pyrroline-*N*-oxide [125]. Iminium ions can be trapped with cyanide as well as detection of the trapped intermediate, and commonly the incorporation of radiolabeled cyanide is used as confirmation of iminium formation [122,126]. Hard electrophiles such as aldehydes are trapped with hard nucleophiles such as semicarbazide [127,128] and methoxylamine [129,130]. Semicarbazide has also been used to identify furan ring opening and thiophene bioactivation.

While the detection of adducts (GSH/NAC/cyano, etc.) early in the drug discovery process provides the information about RM formation, it is absolutely essential that the data need to be placed in proper context before discarding drug candidates associated with this liability. There are numerous examples of drugs that form GSH conjugates in these assays and also exhibit covalent protein binding, but which are not associated with a significant incidence of toxicity. Moreover, toxic drugs that form RMs through non-CYP-mediated bioactivation process will not be detected by the routinely used microsomal assays [131].

6.6.2 Mercapturate (NAC) Conjugate as *In Vivo* Indicators of Drug Bioactivation

A common mechanism for the detoxification of toxic electrophilic compounds occurs via GSH conjugation [16]. The GSH conjugates can be further processed into breakdown products such as mercapturate conjugates (Fig. 6.4) and are excreted in urine [132]. Therefore, mercapturate conjugates are potential biomarkers of bioactivation that are not dependent on cell death to be released into an accessible compartment (e.g., urine) [133]. GSH conjugates are unsuitable biomarkers of metabolic activation *in vivo* because they are only very rarely eliminated in urine and seemingly only at very low concentrations [134]. They have been found as *N*-acetylated derivatives [135].

Human urinary mercapturates have been recognized for many years as particularly useful biomarkers in assessments of human exposure to chemically diverse environmental and biogenic electrophiles [132,136,137]. Recently, through the employment of advanced MS techniques [138], there has been a revival of interest in the bioanalytical possibilities of mercapturates [139,140]. Mercapturate biosynthesis (Fig. 6.4) has been modeled as an interorgan pathway, with the liver serving as the major site of GSH conjugation and the kidney as the primary site for the conversion of GSH conjugates to cysteine conjugates [132,141]; however, in some cases, it can be an entirely intrahepatic process even in rats [142]. GSH adducts of bendamustine are metabolized completely in human liver, only the mercapturates and further metabolites appearing in bile [115]. The cysteine adduct is the sole thioether metabolite of APAP eliminated in human bile, with the APAP cysteine adduct and mercapturate being excreted in urine [143]. Any drug mercapturate produced extrahepatically might also be eliminated in bile: rat liver possesses an efficient mechanism for uptake and biliary excretion of circulating mercapturates [144]. Although the metabolism of GSH adducts can yield numerous S-linked products via modifications of the tripeptide moiety [115,135], as in the case of carbamazepine [145,146] mercapturates are not invariably found among

Figure 6.4 Metabolic activation of APAP. APAP is primarily detoxified by glucuronidation and sulfation in the liver. APAP can also undergo conversion to the chemically reactive species *N*-acetyl-*p*-benzoquinone imine (NAPQI) by cytochrome P450. NAPQI can undergo bioinactivation via GSH conjugation, but when GSH stores are depleted, free NAPQI can oxidize and covalently modify proteins resulting in hepatotoxicity. The toxicological and pharmacological properties of the molecule are a function of the redox potential of the molecule [151].

the excreted metabolites, and there is evidence for a species-selective absence of carbamazepine mercapturates from human urine [145,147]. When considered alongside the frequent observation that a compound can be metabolized to several GSH adducts [145,146,148–150], these findings indicate that a careful analysis of a drug's metabolites is necessary to identify a thioether derivative suitable for use as a biomarker of metabolic activation.

S-Phenyl mercapturic acid and *N*-methylcarbamoyl mercapturic acids have been proposed by American Conference of Governmental Industrial Hygienists (ACGIH) [152] as biomarkers for purposes of evaluating exposure to benzene and *N*, *N*-dimethylformamide, respectively. Among the human pharmaceuticals the mercapturate conjugates (Fig. 6.5) of APAP [143], phenacetin [153], felbamate [154], and valproic acid [155] have been used for the quantitative assessment of *in vivo* bioactivation.

6.7 CASE STUDIES

6.7.1 Acetaminophen

6.7.1.1 The Role of Metabolism in APAP Hepatotoxicity. APAP is a commonly used analgesic and antipyretic, which is safe at therapeutic doses (4 g/day). The pharmacological activity is thought to be attributed to the inhibition of cyclooxygenase activity and a reduction in prostaglandin synthesis [156–158]. However, in cases of overdose, acute liver failure develops that is owing to centrilobular hepatic necrosis. To date, APAP hepatotoxicity still remains a major clinical problem and is the single biggest cause of acute liver failure in the United Kingdom and United States [159]. APAP provides an important tool with clinical relevance to study toxicological consequences of drug metabolism across *in vitro*, *in vivo*, and clinical systems.

At therapeutic doses, about 55% and 30% of renally excreted metabolites are as the glucuronide and sulfate conjugates, respectively [160]. A small proportion of the

Figure 6.5 Mercapturate biosynthesis pathway. Steps are catalyzed by (a) γ -glutamyl-transpeptidase; (b) dipeptidase: cysteinylglycine dipeptidase, and aminopeptidase; (c) cysteine conjugate *N*-acetyltransferase; and (d) *N*-deacetylase [132]. RX, reactive species; Glu, glutamate; and Gly, glycine.

therapeutic dose (5%) is bioactivated primarily by CYP2E1 and also CYP3A4 and CYP1A2 oxidations to the electrophilic intermediate NAPQI [161]. NAPQI is readily detoxified by GSH conjugation and is excreted in the urine as a cysteine or mercapturate product [162].

In cases of overdose, low-capacity sulfation pathways become saturated and a greater fraction of the dose undergoes glucuronidation and oxidation. Under these conditions, NAPQI accumulates and cellular stores of GSH become depleted owing to the shift in NAPQI formation and GSH synthesis (Fig. 6.6) [162–166]. The standard treatment for APAP intoxication is NAC, which replaces hepatic GSH after depletion or conjugates to NAPQI and prevents toxicity, although this is most beneficial if given within 16 h of the overdose.

6.7.1.2 Cellular Consequences of APAP Bioactivation and Bioinactivation. The depletion of hepatic GSH has been shown to be an obligatory step to enable NAPQI to

Figure 6.6 Structures of APAP, phenacetin, valproic acid, felbamate, and their mercapturate conjugates. APAP, acetaminophen; VPA, valproic acid; and FBA, felbamate.

covalently modify and potentially inhibit the function of a number of critical proteins within cells, leading to cell death and has been discussed previously [97]. Examples of critical proteins whose function is inhibited by NAPQI modification include γ -glutamylcysteine ligase catalytic subunit [167], glyceraldehyde-3-phosphate dehydrogenase (GAPDH) [168], aldehyde dehydrogenase [169], and $\text{Ca}^{2+}/\text{Mg}^{2+}$ ATPase [170]. As outlined earlier in the chapter, covalent binding has been hypothesized to contribute to mitochondrial dysfunction, and the resulting disruption in Ca^{2+} and ATP homeostasis is thought to be a critical step in the development of cell death associated with APAP overdose. Moreover, the importance of mitochondrial protein binding in the mechanism of APAP toxicity is highlighted by observations with the nontoxic regioisomer of APAP, AMAP. AMAP undergoes an overall similar level of covalent binding but significantly less covalent binding to mitochondrial protein than APAP [105]. Therefore, the extent of covalent binding and which proteins are modified, rather than covalent binding per se, represent a major factor underlying APAP hepatotoxicity.

The massive chemical stress mediated by an APAP overdose leads to an immediate adaptive defense response in the hepatocyte. This involves various mechanisms, including the nuclear translocation of redox-sensitive transcription factors such as Nrf2, which “sense” chemical danger and orchestrate cell defense. Thus, with respect to APAP, Nrf2-dependent genes of immediate significance are those involved in GSH synthesis such as γ -glutamate cysteine ligase, GSH transferases, glucuronyltransferases, and heme oxygenase. Importantly, it has been observed that nuclear translocation occurs at nontoxic doses of APAP and at time points before overt toxicity [171]. However, with increasing doses of APAP, there is progressive dislocation of nuclear translocation, transcription, translation, and protein activity [167] as the rate of drug bioactivation overwhelms cell defense through the oxidative modification of critical proteins. The cytoplasmic protein Kelch-like ECH-associated protein 1 (Keap1) directly binds to Nrf2 and represses transcription by promoting proteasome-dependent degradation of the protein. It has also been demonstrated that Keap1 is an adaptor molecule for the ubiquitin ligase complex and directs the rapid degradation of Nrf2. When cells are exposed to electrophiles, Nrf2 is liberated from the Keap1-mediated degradation process and accumulates in the nucleus to activate antioxidant response element (ARE)-mediated gene transcription [172]. Somatic disruption of the *Keap1* gene does not interfere with the development of the morphological and physiological integrity of the liver. However, specific knockout of the *Keap1* gene in mouse hepatocytes confers a strong resistance to drug-induced toxicity [172]. This would indicate that the constitutive activation of Nrf2 and concomitantly its target genes is advantageous for mice to overcome xenobiotic toxicity.

6.7.1.3 Inflammation in an Acetaminophen Model of Drug-Induced Liver Injury.

A widely studied model of DILI has been acetaminophen-induced liver injury (AILI) in mice (Table 6.4). Evidence suggests that the initial hepatocellular damage caused by NAPQI may lead to the release of cellular contents known as *damage-associated molecular patterns*. These include High mobility group box protein 1 (HMGB1) and the heat shock proteins that act as signals that can activate cells of the innate immune system, which reside in the liver. This, in turn, leads to hepatic infiltration of inflammatory cells that may contribute to the progression of liver injury by producing proinflammatory mediators such as cytokines and chemokines as well as reactive oxygen and nitrogen

TABLE 6.4 Summary of Inflammatory Models Used in APAP-Induced Hepatotoxicity

References	Inflammatory Model(s)	Reported Effect
100,101	KC depletion	Protection against liver injury at early time points, more susceptible at later time points
114	Neutrophil depletion	Significantly protected against liver injury
102	NK/NKT cell depletion	Significantly protected against liver injury
107	Anti-TNF- α /IL-1- α /IL-1ra	Increased susceptibility to liver injury
106	Anti-TNF- α , TNF-p55 receptor 1 ^{-/-} mice	Reduced mortality and liver injury

species [173]. Neutrophils accumulating in necrotic areas of the liver after APAP overdose were first recognized by Mitchell *et al.*, but the relevance of this accumulation to the pathophysiology is still unclear [174]. A study in C3Heb/FeJ mice revealed that neutrophils accumulate in the liver shortly after hepatic injury, but there was no evidence of neutrophil activation. Additionally, antibodies targeted at these cells did not protect against AILI [175]. In a rat model of AILI, a significant reduction in neutrophil accumulation showed no protection of liver injury [176]. These findings are in contrast to other models in which neutrophils are involved in the course of injury where pretreatment with an antineutrophil antiserum attenuated AILI in rats [177].

Other studies have demonstrated that mice treated with gadolinium chloride to inactivate Kupffer cells (KCs) [178,179] and liposome/clodronate to deplete KCs [179,180] are protected against APAP toxicity. Nevertheless, reports suggest that KC depletion confers protection at early times after APAP treatment [180] but can lead to more severe injury at later time points [179]. The use of an anti-NK1.1 monoclonal antibody to deplete natural killer (NK) cells and natural killer T (NKT) cells significantly protected mice from APAP toxicity probably owing to the reduction in the levels of the proinflammatory cytokine IFN- γ [181]. However, as has been observed with KC depletion, there are also conflicting reports suggesting that NK/NKT cells play little

role in the overall outcome of liver injury in the mouse model of APAP hepatotoxicity [182,183]. This has been supported by a recent study that suggested NK and NKT cells only contributed to liver injury when dimethyl sulfoxide was used to solubilize APAP [183]. Given the contradictory data available on neutrophils and KCs, it is clear that more studies are required to determine their precise role in DILI.

The involvement of various proinflammatory mediators such as TNF- α [184–186], IL-1ra [187], and IFN- γ [181,188], in promoting tissue damage have been demonstrated, whereas other cytokines such as IL-10 and IL-4 [189] have been found to be hepatoprotective in models of APAP hepatotoxicity. Receptors involved in promoting an inflammatory response such as IL-1 receptor [186], p55 TNF- α receptor-1 [185], Toll-like receptors TLR4 and -9 [190,191], and receptor for advanced glycation end products (RAGEs) [192] have been found to be important in promoting an inflammatory response and subsequent pathogenesis.

6.7.1.4 Comparison of the Inflammatory Response in Animal Models of Acetaminophen-Induced Liver Injury. Several different models of DILI in which inflammation has been modulated are being investigated in an attempt to dissect the processes of inflammation from those on DILI. NK and NKT cells were found to play a critical role in the severity and progression of AILI (500 mg/kg, i.p.) by secretion of cytokines and recruitment of inflammatory cells (mainly neutrophils) into the liver [181,193]. An increase of hepatic neutrophil accumulation as early as 4–6 h with a significant threefold increase by 24 h was observed in APAP-treated mice with an associated increase in mRNA levels for cytokines TNF- α and IFN- γ [181]. Depletion of NK and NKT cells (using an anti-NK/NKT cell antibody or an antineutrophil antibody) inhibited liver injury with markedly reduced accumulation of neutrophils in the liver. Subsequent depletion of neutrophils also significantly protected mice against AILI. However, in a recently published fed CD-1 mouse model of AILI, no evidence of hepatic inflammatory cell infiltration was observed over a 24 h time course [27].

Nontoxic doses of APAP (100–400 mg/kg, i.p.) administered 2 h after a dose of Lipopolysaccharide LPS (44×10^6 EU/kg) to fasted C57BL6 mice have been shown to sensitize animals to AILI [194]. Application of LPS led to significantly greater TNF- α production than APAP alone. With APAP treatment alone there was a modest, sustained accumulation of neutrophils from 3 to 24 h after 300 mg/kg APAP. However, neutrophils were not apparent in livers of mice treated with a nontoxic dose of APAP (175 mg/kg), but significant accumulation occurred when this dose was coadministered with a noninjurious dose of LPS. Two hours after treatment with LPS (0 h after APAP), serum TNF- α levels were large and rapidly decreased thereafter, confirming that the inflammatory response observed in this model was due to LPS [194]. These observations support the hypothesis that inflammation induced by LPS and associated elevated levels of TNF- α increase sensitivity to AILI.

Fasted transgenic C57BL6 mice lacking anti-inflammatory mediators such as IL-10, IL-4, IL-6, migration inhibitory factor (MIF), and IL-13 dosed with APAP (200–300 mg/kg, i.p.) displayed increased susceptibility to AILI [189,195–197]. Neutrophils were found to accumulate to a greater extent in IL-13 knockout (KO) mice than wild type (WT) treated with APAP with the level of TNF- α , IL-6, and IFN- γ increased at 4 h in WT and IL-13 KO APAP-treated animals compared to saline-treated controls [197]. These data suggest a hepatoprotective role for anti-inflammatory mediators in these models and that the balance between the Th1 and Th2 response

is an important determinant for AILI. To test this hypothesis, susceptibility to AILI was compared between two mouse strains, C57BL/6 (more susceptible to AILI and that develop predominantly a Th1 response) and BALB/c (less susceptible to AILI and that develop a Th2 response). About 24 h after exposure to APAP C57BL/6 mice produce high levels of TNF- α (proinflammatory), whereas levels in BALB/c mice show no difference. On the other hand, IL-6 (anti-inflammatory) levels were higher in BALB/c than C57BL/6 24 h after administration. These data support the hypothesis that AILI is associated with a Th1-dominant response in Th1/Th2 cytokine balance and TNF- α may play a role in toxicity [196].

However, the role of TNF- α remains controversial with contradictory reports, suggesting that TNF- α is involved in pathogenesis of DILI [185,186]; it is not involved in toxicity [27,184,185,187,189–198]; or it has a role in defense against toxicity and repair [199,200]. Data suggest that as most cytokines the effects of TNF- α in liver toxicity are pleiotropic with other cytokine networks being involved and it is the interplay between these different cytokine cascades that determine the nature of the inflammatory response associated with toxicity. Furthermore, the understanding of the regulatory mechanisms in the context of DILI that control the potential for damage-associated molecular pattern molecules or cytokines to activate immune cells and initiate an inflammatory response require further investigation. For example, recent evidence suggests that the caspase-dependent oxidation of HMGB1 is critical for inhibiting its immune stimulatory potential following apoptosis [27].

As well as APAP, other model hepatotoxins have been used to investigate the role inflammation plays during DILI (Table 6.5). Given the complexity of interplay between chemically mediated toxicity and inflammation and the differences observed between strains of mice, species, and *in vivo* model pretreatment, further investigation is required to define the precise role a cytokine has in response to the chemical insult or as part of the inflammatory response. Once this has been defined, then the value of the cytokine as a biomarker can be assessed.

6.7.1.5 APAP Toxicity and Circadian Rhythm. Susceptibility to AILI has been reported to follow a circadian rhythm [201,202]. Rodents administered with APAP at the start of the circadian light phase (early subjective day) were more protected than those dosed at the start of the dark phase (early subjective night). This temporal difference in hepatotoxicity can be explained by concomitant changes in drug disposition. Hepatic GSH content fluctuates over a 24-h cycle linked closely with feeding patterns. In rodents, GSH abundance peaks at early morning and reaches a nadir at early night. This reduction in GSH lowers the potential for the liver to bioinactivate NAPQI and allows the chemically RM to cause extensive damage as defined by serum biomarkers

TABLE 6.5 Inflammation in Other Models of DILI

DILI Model	Inflammatory Factors Investigated	References

Galactosamine + LPS	TNF- α , TNF-p55 receptor	133,134

of DILI. Moreover, it has also been shown that the bioactivation pathway, Cyp2e1-mediated biotransformation of APAP, does not remain constant over the course of the day. Cyp2e1 has been shown to exhibit a mild oscillation with an increased expression at early night. The molecular mechanism underlying Cyp2e1 oscillation has been suggested to be linked with hepatocyte nuclear factor 1 α (HNF1 α) and the biological clock [203], but other mechanisms have been suggested, for example, diurnal rhythms in liver energy status. This parallel of increased bioactivation and reduced bioinactivation over the light phase in the rodent model increases the exposure of the liver to the toxic metabolite and suggests the temporal variation in APAP-induced hepatotoxicity.

6.7.2 Nefazodone

Nefazodone is an antidepressant that was withdrawn from the US market in 2004, following withdrawal in Canada and Europe, owing to incidences of hepatotoxicity. A black-box warning for hepatotoxicity stated that there was one case of liver failure resulting in death or transplant per 250,000–300,000 patient years and more than 20 deaths were reported to the FDA [204]. Patients who presented with nefazodone-induced hepatotoxicity did so 1–8 months after commencement of treatment and had been taking a dose of 200–400 mg daily [204–206]. In those patients with acute liver failure, histology demonstrated bile duct proliferation, cholestasis, and centrilobular necrosis [205]. It is still unclear how nefazodone caused hepatotoxicity in man and the three mechanisms currently presented in the literature are discussed below.

6.7.2.1 Reactive Metabolite Formation and Covalent Binding. Nefazodone is predominantly metabolized by CYP3A4 [207]. During metabolism in human and rat liver microsomes, it is bioactivated to several quinone imine and iminium ions that can be trapped with GSH and cyanide, respectively (Fig. 6.7) [39,208]. The major quinone imine is formed from hydroxylation para to the piperazinyl nitrogen that can then undergo two electron addition to form the corresponding quinone imine [208]. The bioactivation of nefazodone *in vitro* has led to the investigation of binding to liver protein as a mechanism of toxicity. It has been shown to covalently bind to human liver protein in microsomes, S9 fraction, and hepatocytes [39,208,209]. In human liver microsomes (HLMs), it has been demonstrated to bind at 1364 pmol/mg protein [209], a level of binding over 20 times that of the 50 pmol/mg threshold, which Evans *et al.* suggested as an upper level of “safe” binding. This binding was significantly reduced to 306 pmol/mg with a mixture of Uridine 5'-diphospho-glucuronic acid (UDPGA) and GSH and 254 pmol/mg in the more complete metabolizing system of hepatocytes. Studies that took into the account the intrinsic clearance also showed that there was a high rate of binding in liver microsomes [210]. Although it has been established that nefazodone covalently binds to liver protein, there is currently no literature that indicates which proteins are the binding targets of nefazodone and whether this binding may contribute to cell death.

6.7.2.2 Role of Bile Salt Export Pump (BSEP) Inhibition in Nefazodone Toxicity. Nefazodone is predominantly excreted in the bile. Approximately 60% of radiolabeled nefazodone that was intravenously administered to dogs was excreted in the feces [211] and in humans 49% of nefazodone was cleared in the urine [212], suggesting that the other route of clearance was through bile. Bile salt export pump (BSEP) is a

Figure 6.7 Characterized bioactivation pathway of nefazodone in human liver microsomes [122].

member of the ATP-binding cassette transporters and mainly responsible for the transport of bile salts and any other cholephilic compounds across hepatocytes from the blood plasma and into the bile canaliculi [213]. There have been investigations into the inhibition of BSEP as a cause of nefazodone hepatotoxicity [214]. Sandwich human hepatocytes, expressed BSEP in membrane vesicles and rats, were used to investigate the potential for nefazodone to be causing toxicity through inhibition of hepatobiliary transport [214]. Nefazodone caused a concentration-dependent inhibition of taurocholic acid in canaliculi with an $IC_{50} = 14 \mu M$ [214]. As the hepatocytes were fully capable of metabolism, it was not clear whether metabolites or parent compound was causing the inhibition. This led to the investigation of BSEP-mediated transport inhibition activity in membrane vesicles, which again resulted in concentration-dependent inhibition of taurocholic acid transport with $IC_{50} = 9 \mu M$ [214]. This suggested that the parent compound of nefazodone was causing the inhibition and not metabolites. The authors also explored the toxicity of nefazodone in hepatocytes using protein synthesis as an indicator of toxicity. Nefazodone produced a concentration-dependent decrease in protein synthesis. The effect of metabolism on toxicity was also considered, the authors used 1-aminobenzotriazole (ABT), a nonspecific inhibitor of CYP, to inhibit the metabolism of nefazodone in hepatocytes [214]. Incubation with nefazodone and ABT for 24 h resulted in a 45% decrease in total protein synthesis. Nefazodone alone resulted in almost full recovery after 24 h. This indicates that the bioactivation and covalent binding of nefazodone may not be the cause for hepatotoxicity.

6.7.2.3 Role of Mitochondrial Dysfunction in Nefazodone Toxicity. Increasingly, mitochondrial toxicity is being implicated in drug-induced organ toxicity. Patients with

underlying mitochondrial diseases may not have any symptoms until additional stress is placed on the mitochondria, such as drug-induced oxidative stress, that results in organ toxicity. As described earlier, the effect that nefazodone has on the mitochondria and the resulting hepatotoxicity has been investigated in isolated OXPHOS complexes, HepG2 cells, and sandwich human hepatocytes [89]. It has been demonstrated that in isolated OXPHOS complexes nefazodone inhibits complex I ($IC_{50} = 14 \mu M$) [89]. Using culture medium in which the primary energy source, glucose, has been replaced with galactose, HepG2 cells, which are more reliant on oxidative phosphorylation, exhibits 100% depletion of ATP when treated with $200 \mu M$ nefazodone [89]. A concentration curve in galactose grown HepG2 cells results in an $IC_{50} = 9 \mu M$ [89]. The HepG2 cells did not express CYP3A4, again suggesting that metabolism is not required for toxicity. Investigations of mitochondrial injury were also carried out in sandwich human hepatocytes. This resulted in significant cell loss, increased ROS, elimination of mitochondrial membrane potential, and depletion of intracellular GSH [89]. Maximum plasma concentrations of $2\text{--}4 \mu M$ has been reported in patients taking $200\text{--}400 \text{ mg/day}$, although there is no available data on plasma:liver ratio of nefazodone [215]. However, if nefazodone does inhibit its own excretion as discussed above, then accumulation in the liver could reach levels similar to that seen *in vitro*.

6.7.3 Acyl Glucuronides

Human populations are exposed to numerous chemical entities possessing a carboxylic acid moiety, including nonsteroidal anti-inflammatory drugs (NSAIDs), hypolipidemic drugs (clofibrate), anticonvulsants (valproic acid), and diuretics (furosemide). Several carboxylic acid drugs have been withdrawn from the market over the years as a consequence of rare but occasionally severe adverse effects. From a toxicological perspective, attention has been focused on the bioactivation of this functional group to form RMs, namely, coenzyme A thioesters and acyl glucuronides (AGs) [63], implicating drug bioactivation as an early step in the pathogenesis of ensuing adverse effects. Acyl glucuronidation represents one of the metabolic pathways in the elimination of many carboxylic-acid-containing drugs and metabolites [216], and therefore as a physiological clearance process is potentially important to the pharmacological effects of those compounds. This reaction is catalyzed by multiple human UDP-glucuronosyltransferases (UGTs) [217,218]. Generally, glucuronides are not only less biologically active than the parent aglycone [219] but also subject to more rapid biliary excretion because of their enhanced affinity for transporter proteins [220–225]. However, AGs represent an exception to this accepted principle, possessing intrinsic electrophilic reactivity. This reactivity is manifested through three main pathways: hydrolysis; acyl migration, and irreversible binding with cellular macromolecules. As a number of carboxylated drugs known to form AG metabolites are associated with ADRs in patients, AGs have come to be almost generically implicated in the possible causation of these toxicities. Although bioactivation liabilities connected with oxidative metabolism appear to have caused concern much more frequently than acyl glucuronidation [116] and initiate increasingly sophisticated structural optimization programs to minimize bioactivation [226], medicinal chemists have still derived reassurance from any evidence that an AG metabolite of a new drug is relatively stable [117,227,228]. As a further indication of an established perception of toxicological risk, attempts to connect drug metabolites with the toxicity that has forced the withdrawal

of a compound from development, as in the recent case of torcetrapib [229], still consider the possible involvement of AGs. Torcetrapib, a cholesteryl ester transfer protein inhibitor, was terminated in phase 3 trials because of an unexpected increase in cardiovascular events and death [230]. Administration of torcetrapib was shown to acutely increase blood pressure in both rodent and nonrodent species [230]. Glucuronide conjugates of two major carboxylic acid metabolites can be detected in different species [229]. What may be characterized as a lingering but ill-defined anxiety seems to surround drugs that are metabolized extensively to AGs in humans. Nevertheless, with the notable exception of the acute enteral toxicity of DCF in rats [231], the toxicological implications of AG formation have not been delineated clearly *in vivo*. Certainly, the use of probenecid [232] and the recent developments of bicifadine [233] and deferasirox [234] have continued, despite these drugs being metabolized by humans to unstable AGs.

6.7.3.1 Acyl Glucuronide Reactivity. The reactivity of an AG derives ultimately from the electrophilicity of its ester carbonyl group resulting in hydrolysis to the parent aglycone, intramolecular rearrangement, and intermolecular transacylation reactions. A structure effect on the degree of reactivity has been demonstrated with the rate order: acetic acid > propionic acid > benzoic acid derivatives. It was proposed that this order could be attributed to the inherent electronic and steric properties of each specific aglycone [235]. Consequently, as a number of drugs are associated with AG formation but not necessarily toxicity, the reactivity of the corresponding AGs has been under much investigation with the aim to delineate a relationship between AG reactivity and ensuing toxicity.

1- β -*O*-Acyl glucuronides may undergo intramolecular rearrangement through the migration of the acyl group to positions C-2, C-3, and C-4 of the carbohydrate moiety [236] (Fig. 6.8). The mechanism is thought to involve nucleophilic attack by the hydroxyl group on the adjacent carbon to generate an *o*-acid ester intermediate [237,238]. The intramolecular rearrangement of AGs is of particular importance because it leads to re-exposure of the hemiacetal function of the glucuronic acid moiety, thus allowing two chemical reactions: anomerization and nonenzymatic glycation [239]. Stability and, therefore, reactivity of the AG could potentially have significant implications on the likelihood of a drug causing toxicity.

In addition, 1- β -*O*-acyl glucuronides are particularly susceptible to hydrolysis, resulting in the release of the parent aglycone. A number of catalysts, including β -glucuronidases, nonspecific esterases, serum albumin, and hydroxide ion, can be involved in this reaction. The rate of hydrolysis is dependent on a range of parameters including pH, temperature, and aglycone structure [241]. It has been determined that the rate of hydrolysis, in parallel with acyl migration, can be a relevant parameter to investigate in connection to AG reactivity with cellular macromolecules [242]. An almost linear correlation ($r^2 = 0.995$) between the overall degradation rate (hydrolysis and intramolecular rearrangement) of AGs and the amount of drug bound to Human serum albumin (HSA) *in vitro* was reported for 9AGs. Subsequent investigations of AG reactivity also resulted in similar results with an improved correlation obtained when the fraction of bound drug (as a percentage of initial glucuronide present) was plotted against the degradation rate [235,243]. Exact degradation half-lives are variable across the AGs and is most likely dependent on the structure of the aglycone [244].

Figure 6.8 Mechanisms of AG rearrangement and covalent binding to protein. Rearrangement of the AG is shown, as the aglycone moves around the ring to the 2-, 3-, and 4-glucuronide positions. An example of rearrangement between the β and α positions is shown by the 3-isomer, with its corresponding covalent binding to protein via the glycation mechanism. This also occurs for the 2- and 4-isomers. Covalent modification of protein by the transacylation pathway is represented by the 1 β isomer. RCOO⁻ represents the aglycone. X represents nucleophilic groups on proteins susceptible to covalent adduct formation from the AG through transacylation. *Source:* Adapted from Bailey *et al.* [240]. (See color insert.)

The electrophilic properties of AGs also enable them to covalently bind to specific nucleophilic sites on biological macromolecules. While this reaction is considered to be a quantitatively a minor pathway of AGs, it has been implicated in the underlying mechanism of toxicity of certain carboxylic-acid-containing drugs such as hypersensitivity reactions [237,245–247]. Specifically, these immune-mediated reactions are governed by the generation of neoantigens, formed as a result of RMs binding to hepatic protein. These immunogenic adducts are then recognized by the immune system and elicit either antibody [107,173] or cytotoxic T-cell responses [173,245].

Several studies have been carried out to elucidate the mechanism for the formation of protein covalent adducts, with two pathways identified. The first is a transacylation mechanism involving nucleophilic displacement of the glucuronic acid from the ester group by macromolecular nucleophilic sites such as $-\text{NH}_2$ of lysine residues [248], $-\text{SH}$ of cysteine residues [249], or $-\text{OH}$ groups from tyrosine residues [250]. An alternative mechanism reported is the glycation pathway, where the aglycone moiety forms a protein adduct via the glucuronic acid moiety. Specifically, this requires acyl migration before binding, enabling the ring opening of the carbohydrate moiety and subsequent

anomerization. This results in the formation of open-chain aldehyde intermediates and the further condensation of the aldehyde group with the amine groups on lysines or DNA nucleosides to form imines (Schiff bases), which can further undergo rearrangement to a more stable 1-amino-keto-product (Amadori rearrangement) [251–254].

The formation of protein adducts is not only limited to plasma protein alone but can also involve other organs including the liver, kidney, skeletal muscle, and intestine, indicated by a number of animal studies [255,256]. Therefore, the formation of AGs could have implications in specific organ-directed toxicities and also systemic hypersensitivity reactions through both the binding to specific organs and plasma protein. However, the toxicological significance of covalent binding between drug and macromolecule remain speculative and still require definitive proof as protein adduct formation does not always lead to toxicity. This concept is best illustrated by APAP and its structural isomer AMAP, where AMAP at the same molar dose as APAP was found to covalently bind to cellular protein and yet did not result in toxicity. This introduced the concept of the critical protein hypothesis, delineating certain proteins as critical targets in hepatotoxicity [18,105]. Supporting this, the RM of APAP, NAPQI binds to a number of proteins. In mice, one of the major targets of NAPQI is urate oxidase, an enzyme lost during primate evolution. As a result, it is thought unlikely that irreversible binding to urate oxidase represents a role in APAP-induced hepatotoxicity in mice, as both humans and mice develop centrilobular necrosis with similar per kilogram doses [257]. This highlights the need to identify the critical protein adducts involved in the mechanism of toxicity.

Glucuronides of propionic acids have been reported to be more stable and less chemically reactive than those formed from acetic acid NSAIDs, generally possessing a much longer half-life *in vitro* at physiological pH. It is thought that this can most likely be attributed to the steric hindrance and electron donating effects of the α -methyl group [247]. Despite this, Benoxaprofen BNX-AG has been reported to react with HSA *in vitro*, forming protein adducts through both transacylation and glycation pathways [257]. The use of tandem mass spectrometry further enabled the identification of specific binding sites, which included Lys-159 and Lys-199 to a lesser extent. Ser-312, Ser-480, and Arg-222 were the other three major binding sites, which reacted only via nucleophilic displacement.

It is, therefore, well established that AGs are intrinsically reactive electrophiles, with the potential to bind to cellular macromolecules. However, the contribution of AG formation to underlying toxicological mechanisms remains unclear and is consequently under much investigation.

6.7.3.2 Toxicological Implications of Acyl Glucuronides. A number of carboxylate drugs have been found to undergo extensive metabolism to an AG, but with varying degrees of toxicity associated with administration. Specifically, the use of DCF has been associated with a number of adverse effects, the most prominent being induction of hepatic injury [242,258–261]. It has been reported that 15% develop abnormalities in aminotransferase plasma levels [258,262]. Cases of severe hepatic reactions are much rarer in frequency with estimates ranging from 1–2 cases per million prescriptions [263] to 6–18 cases per 100,000 person years [264]. Published cases of severe DCF hepatotoxicity equate to ~250 reports with a case fatality rate of 10% [265]. The high case numbers can be attributed to the large number of patients who

are prescribed DCF worldwide [76]. The injury associated with DCF-induced hepatotoxicity is consistently hepatocellular, resembling hepatitis, characterized by jaundice, and to varying degrees, fatigue anorexia, nausea, and vomiting [262]. The underlying pathogenesis associated with DCF hepatotoxicity is unknown, but drug bioactivation has been implicated. Consequently, investigations have been undertaken to delineate the importance of AG reactivity and to a lesser degree AG exposure.

The majority of investigations concerning AG adduct formation have focused on binding to HSA, which would explain systemic adverse effects associated with carboxylate drugs. However, certain drugs are associated with specific organ-related toxicity, such as DCF, which represents a paradigm for idiosyncratic hepatotoxicity. Consequently, the focus of investigations has centered on assessment of binding directly to liver macromolecules. In rodents, the majority of adducts were located on the canalicular plasma domain of the hepatocytes [266,267]. In addition, DCF adducts were also identified on the apical domain of enterocytes; however, it has not been conclusively proven that these are as a result of AG formation [268]. DCF adduct formation with enterocytes through acyl glucuronidation has been suggested based on a study by Seitz *et al.* [267] whereby administration of bile containing DCF-AG resulted in intestinal ulcer formation in Multidrug resistance-associated protein 2 MRP2-deficient rats, which did not occur when DCF alone was administered. The ability of DCF-AG to bind to serum albumin has yet to be determined in either *in vitro* or *in vivo*.

6.7.4 Nevirapine

Nevirapine (NVP) is a highly effective nonnucleoside reverse transcriptase inhibitor (nnRTI) used in the treatment of HIV-1 infection. NVP is used widely in developing countries as it is inexpensive and does not require refrigeration; however, it is associated with clinically restrictive side effects, skin reaction and hepatotoxicity that can occur either simultaneously or separately. Toxicity is thought to be mediated through RM formation either directly or through the induction of the immune system. Although NVP is highly effective, the incidence of severe or life-threatening hepatotoxicity has led to the FDA giving a black-box warning. The nature of NVP-induced liver injury is not clear; cases of hepatotoxicity vary in terms of severity, time to onset, and can occur with or without hypersensitivity reactions [269,270]. It is possible that the late-occurring reactions may be nonimmune in nature, while those occurring in the first three months may have an immune pathogenesis [271]. The time of onset and the nature of the NVP-induced skin rash suggest that the reaction is immune mediated and because of the low incidence it is likely that the reaction may be idiosyncratic [271,272].

6.7.4.1 Possible Pathways of Nevirapine Bioactivation. There appear to be several pathways for NVP bioactivation (Fig. 6.9). The cyclopropylamine group has the potential, via N-dealkylation, to become bioactivated to an aminium cation radical [120]. 12-OH NVP, a major metabolite in HLMs, is a substrate for sulfotransferase in rats [272], and it has been proposed that the sulfate ester dissociates to form a reactive quinone methide intermediate [272]. The quinone methide could also be generated, additionally or alternatively, by enzymic oxidation [117]. Hydroxyheteroaryl metabolites [273] are potential precursors of reactive quinone imines [117]. Finally, NVP might form one or more heteroarene epoxide intermediates in either of the pyridine

rings. Novel NVP GSH conjugates and mercapturates, potentially formed from multiple RMs, have been characterized [274]. Mercapturates were isolated from rat bile and characterized definitively by NMR as thioethers substituted at the C-3 and exocyclic C-12 positions of the methylpyridoring of NVP. It is proposed that NVP undergoes bioactivation to arene oxide and quinone methide intermediates [274]. Further evidence for metabolic activation of NVP includes NADPH-dependent irreversible binding of radiolabeled drug to rat liver microsomes (RLMs) [120], mechanism-based inhibition of microsomal CYP3A4 [117], and the metabolism of NVP by HLM and CYP3A4 to a single GSH adduct [117].

6.7.4.2 Animal Model of Nevirapine-Induced Skin Rash. Uetrecht and colleagues have characterized extensively a dose-dependent, NVP-induced skin rash in female Brown Norway (BN) rats that resembles the idiosyncratic cutaneous reaction seen in humans [275,276] and appears to be immune mediated [277]. The NVP-induced skin rash in BN rats is similar to that in human in terms of: the time of onset, sex dimorphism, the fact that incidence increases with dose, that an escalating dose of NVP can reduce incidence, and that rechallenge in rats and humans results in more severe rashes than on initial exposure [275]. Chen *et al.* [272] have proposed that the skin rash induced by NVP and 12-OH NVP in BN rats may be due to NVP quinone methide formed through dissociation of 12-OH NVP sulfonate in the skin. A mild hepatotoxicity, assessed by histopathological and plasma enzyme indicators, is induced in rats pretreated with NVP or dexamethasone [278]. This implies one or more NVP metabolites are causal agents of hepatotoxicity but no mechanistic explanation of the liver injury has emerged. Chen *et al.* [272] have suggested that the hepatotoxicity of NVP in humans is due to quinone methide formed *in situ* by CYP enzymes.

Evidence suggests that the 12-OH NVP pathway is responsible for NVP-induced skin rash, as administration of 12-OH NVP induces skin rash at 50 mg/kg/day as opposed to 150 mg/kg/day with NVP [272]. Cotreatment with ABT decreased urinary excretion of 2-OH NVP, 3-OH NVP, and 4-COOH NVP while increasing the urinary excretion of 12-OH NVP. The result was the formation of skin rash at 50 mg/kg/day in female BN rats and at 150 mg/kg/day in male BN rats, which normally unaffected [272]. However, on rechallenge, 12-OH NVP failed to elicit a skin rash, even if the initial rash was induced by 12-OH NVP [272]. It may be that NVP is needed to induce the CYP isoforms required for bioactivation to RM.

6.7.4.3 Potential Markers of Nevirapine Bioactivation. Novel NVP GSH conjugates and mercapturates, potentially formed from multiple RMs, have been characterized [274]. The formation of drug-GSH conjugates is often used as an indicator of bioactivation. GSH conjugates are generally excreted in the urine as mercapturates. Drug mercapturates have been used as biomarkers of exposure to an RM [154,155]. The identification of two novel NVP mercapturates in humans and rats and the development of a mass spectrometric assay to quantify them pose the opportunity to develop the mercapturates as biomarkers of NVP-induced skin rash [274]. To justify the use of a NVP mercapturate as a biomarker of exposure to an RM, a direct link between mercapturate formation and adverse event must be confirmed; the female BN rat model of NVP-induced skin rash can be utilized to do this. A direct link between mercapturate formation and skin rash incidence could be proved by using specific CYP450 inhibitors to modulate NVP metabolism.

6.8 SUMMARY POINTS

- There is overwhelming evidence to suggest bioactivation of drugs to chemically reactive metabolites (RMs) plays a major role in toxicity and ADRs.
- Chemically RMs can induce oxidative stress in the cell by introducing electrophilic species, stimulating production of ROS and disrupting thiol status through depletion of GSH.
- The cell can activate an immediate adaptive defense response via the upregulation of gene expression when the cell undergoes oxidative stress.
- If the oxidative insult overwhelms the cell's protective mechanisms cell death can ensue through a number of mechanisms, including mitochondrial dysfunction, DNA damage, protein binding, and induction of the immune response and inflammation.
- As a result of drug attrition occurring late in drug development—one of the main reasons for which is related to safety—we need to be able to detect the ability of a NCE to be bioactivated and whether the reactive intermediate is likely to cause hazards.
- Many pharmaceutical companies have used covalent binding to microsomal proteins as an indicator of a safety liability. However, the degree of covalent binding in microsomes is an indicator of bioactivation, but is not always indicative of toxicity and, hence, is poorly translated into safety outcomes in the clinic covalent binding. Work is currently ongoing to develop relevant human hepatic cell lines as an alternative to microsomes with the hope of generating a more physiologically relevant system and improving clinical translation of data.
- The development of clinically relevant biomarkers, which can successfully assess the propensity of a chemical to cause toxicity and will bridge the “disconnect” between preclinical *in vitro* and *in vivo* studies and clinical studies, in terms of successful prediction of safety liability, is crucial.

7.1 SUMMARY

Over the past two decades, drug metabolism has become an indispensable component of both research and development activities in the pharmaceutical industry, where it has played an increasingly important role in support of the safety assessment of new chemical entities (NCEs). In response to recent regulatory guidance on the safety evaluation of metabolites of candidate drugs in man, novel approaches have been adopted to define the identities and levels of circulating metabolites in the plasma of both human subjects and the animal species employed in safety assessment programs. Through these analyses, exposure margins are established for human drug metabolites that circulate above a certain threshold in order to provide assurance that the preclinical toxicology program takes into account metabolites of the drug candidate as well as the parent molecule. Metabolites judged to be “disproportionate” or “unique” by regulatory criteria may require more detailed evaluation. In considering the factors that need to be taken into account in assessing the safety of metabolites of NCEs, it is appropriate to classify biotransformation products into two categories based on their chemical reactivity, viz. “stable” and “chemically reactive.” The different experimental approaches employed to study these two groups are outlined and the implications of the findings for lead optimization efforts in drug discovery, and for later phase clinical development programs, are discussed in the context of establishing the human safety of the NCE.

7.2 INTRODUCTION

Traditionally, the primary focus of safety assessment paradigms in pharmaceutical development centered on measuring exposure to the drug candidate itself, first pre-clinically in animal models to support first-in-human studies and, subsequently, during clinical trials to establish appropriate safety margins for continued clinical development. However, with the advances that have occurred over the past two decades in the field of drug metabolism [1], notably in bioanalytical technologies for the detection, identification and quantitative analysis of drug metabolites, and in the tools of molecular biology that have enabled studies on the biological function and regulation of drug metabolizing enzymes and transporter proteins, increased attention has been paid to the pharmacological and toxicological importance of drug *metabolites* in the drug discovery and development process. Indeed, the level of scrutiny of biotransformation products has been heightened by the growing awareness that the adverse effects of many foreign compounds may be attributed, at least in part, to the actions of one or more metabolites of the administered agent, and it is in this context that drug metabolism as a discipline has become an integral component of the safety evaluation of NCEs [2]. Regulatory guidance documents now have been published on the safety assessment of drug metabolites [3,4], with an emphasis on those biotransformation products that circulate (or are anticipated to circulate) in human plasma, the overall goal of which is to provide assurance that preclinical safety findings are relevant to the human situation in terms of exposure to both parent drug *and* its circulating metabolites. For purposes of discussion, drug metabolites may be divided into two broad categories, namely, those that are sufficiently stable to be isolated from biological fluids and characterized by conventional analytical techniques [e.g., liquid chromatography–tandem mass spectrometry (LC-MS/MS) and nuclear magnetic resonance (NMR)], and those that are chemically reactive in nature and rarely are detected as the native species, but whose existence may be inferred from stable downstream products of further biotransformation [e.g., conjugates with glutathione, γ -glutamylcysteinylglycine (GSH)]. In general, these two groups of metabolites act to cause toxicity by different mechanisms, distinct approaches are employed to study them, and the implications for drug development associated with stable versus reactive metabolites also differ. At the heart of the matter in both cases, however, is the question of predicting drug toxicity in humans from results obtained in animals, where species differences in drug metabolism (which normally are quantitative, rather than qualitative) may confound the interpretation of animal toxicology data in terms of human risk assessment [5].

7.3 STABLE DRUG METABOLITES

The issue of addressing, in a systematic manner, the involvement of stable drug metabolites as a key component of the safety assessment of new drug candidates was first highlighted in a position paper coauthored by representatives of member companies of the US Pharmaceutical Research and Manufacturers Association (PhRMA), which proposed a number of practical approaches to the problem [6]. This publication, which became known as the *MIST* (“Metabolites in Safety Testing”) document, proposed *inter alia* that those small molecule drug metabolites whose exposure in humans [as measured by area under the plasma concentration versus time curve (AUC_p) values]

exceeded 25% of that of the respective parent drug be viewed as “major metabolites” and that only such metabolites should be given further consideration in terms of verifying systemic exposure in one or more of the animal species employed in the preclinical safety assessment program. Recommendations also were made as to the specific, albeit very rare, case of a “unique” human metabolite, defined as a product of biotransformation that is detectable only in humans and not in any of the animal species investigated. In the years following publication of the MIST paper, numerous commentaries have appeared dealing with different aspects of the issue, such as whether absolute, as opposed to relative, metabolite exposure should trigger further safety evaluation of a given metabolite [7], the importance of the human radiolabeled absorption, distribution, metabolism, and excretion (ADME) study as the primary source of information on human metabolites for decision-making purposes [8], the impact of duration of drug administration on potential metabolite-mediated toxicity [9], and consideration of mechanisms of toxicity with regard to parameters such as dose, abundance, and duration of therapy [10]. Clearly, the challenge of addressing, in a comprehensive fashion, the safety of human drug metabolites is a complex and multifaceted issue.

In 2008, the US Food and Drug Administration (FDA) published a guidance document entitled “Safety Testing of Drug Metabolites” [3], which outlined the Agency’s views on best practices in this area. In some respects, this guidance paralleled the recommendations of the MIST paper [6], but differed significantly in other respects, notably in defining the threshold for human metabolites of interest as those whose AUC_p values exceeded 10% of that of the parent drug when measured under steady-state dosing conditions. Moreover, it was recommended that metabolites falling into this category should be demonstrated to be present in the plasma of at least one of the animal species selected for preclinical safety assessment at levels at least as great as those observed (or predicted) in human subjects at the highest clinical dose. Should this requirement for exposure margins (i.e., $\text{animal } AUC_p \geq \text{human } AUC_p$) not be met, then the metabolite in question is designated “disproportionate,” and additional safety studies may be required to assure its human safety. While in some cases, metabolite exposure in animals can be increased by administering progressively higher doses of the parent drug, this approach is not always successful because of a number of factors, for example, limited solubility in the dosing vehicle, saturation of drug absorption, and species differences in metabolic pathways. In these instances, the FDA guidance recommends that separate animal toxicology studies with the preformed (synthetic) metabolite should be considered. There appears to be general agreement that drug conjugates present in the systemic circulation do not, in general, pose a safety concern, although the FDA guidance singles out acyl glucuronides as being “toxic molecules,” a curiously broad generalization. Finally, the guidance emphasizes the need for information on human drug metabolism to be acquired as early as possible in the drug development process so that issues related to disproportionate human metabolites may be recognized and addressed before the initiation of large-scale (phase III) clinical trials.

The recommendations of the FDA guidance on MIST have a number of significant implications for the pharmaceutical industry, and many companies have revised (or are reviewing) their approaches to assessing the role of drug metabolites in the safety evaluation of NCEs. Central to many of the concerns over the MIST guidance are practical limitations that pertain to the conduct of drug metabolism studies in support

of drug development [11,12]. For example, it is widely accepted that the “gold standard” approach to quantitative metabolic profiling in human subjects is the radiolabeled ADME study [8,13], which typically is not performed until a relatively late stage of development (usually following the phase IIA proof-of-concept trials) and involves the administration of a ^{14}C -labeled variant of the drug candidate as a single dose; thus, definitive information on the presence of a disproportionate metabolite may not be available early in the development process, and the data would not be obtained under steady-state conditions which require a multiple-dose design. Moreover, any approach to assessing the toxicological properties of a drug metabolite that involves administration of the preformed compound is fraught with difficulties because of potential differences in the disposition of that metabolite when dosed as the synthetic material versus when the metabolite is formed *in vivo* from the parent drug [14,15]. Indeed, chemical synthesis of the metabolite of interest on a scale appropriate for *in vivo* studies may not be straightforward, particularly when issues of stereochemistry are taken into account, such that considerable time, effort, and financial resources may need to be expended for questionable return. Also, the 10% “cut-off” for a metabolite-of-interest seems unduly stringent, given that many situations are known in which the parent drug is a quantitatively minor contributor to the total drug-related material in human plasma due to extensive first-pass metabolism; in such cases, numerous circulating metabolites could exceed the 10% threshold and, if not present at exposure multiples greater than $1 \times$ in animals would require separate toxicology testing. Clearly, the resource implications associated with addressing these issues are nontrivial, and the scientific value of conducting such studies in many cases may be marginal at best and misleading at worst.

Interestingly, the International Conferences on Harmonization (ICH) counterpart of the FDA MIST guidance, termed *document M3* [4], also adopts a 10% threshold for circulating drug metabolites but references this value to “total drug-related exposure” and not to parent drug alone. This is a significant difference between the two regulatory guidances, and begs the question of how best to determine “total drug-related exposure” early in the drug development process, before the conduct of the radiolabeled human ADME study. Also, ICH M3 makes no mention of metabolite assessment under steady-state conditions and also suggests that the above 10% figure may be relaxed somewhat for therapeutic agents that are to be administered at a daily dose of <10 mg. How these differences between the FDA and ICH guidances will be resolved remains to be seen, although it is anticipated that the ICH guidance will take precedence. Regardless, it is apparent that in the future drug metabolites will be the focus of much greater regulatory scrutiny from a drug safety perspective than has been the case in the past.

In response to the guidances dealing with the issue of drug metabolites in drug safety evaluation, numerous publications have appeared dealing with topics such as new (nonradioactive) methodologies for detecting, identifying, and quantifying metabolites from both animal studies and early (first-in-human) clinical trials, based on NMR spectroscopy [16,17] and LC-MS/MS with high resolution mass analysis [18–22]. An alternative approach that retains the use of radioactivity for early human metabolism studies is the “microdose” technique, in which a very low dose of ^{14}C -labeled drug (typically $100\text{ }\mu\text{g}$ or less and $<1\text{ }\mu\text{Ci}$) is administered to volunteers in what may be regarded as a “pilot” human ADME study, and metabolite profiles in plasma determined by the combined use of (off-line) liquid chromatography (LC) and accelerator mass spectrometry (AMS) [23]. Since both the mass of drug candidate and the dose

of radioactivity are extremely low, such “Phase 0” human studies can be supported by a much-abbreviated preclinical safety package, thereby economizing on time and resources. However, this approach suffers from the limitation that, while radiochromatographic metabolite profiles can be reconstructed for the drug candidate of interest, no structural information is available from AMS, and therefore, additional work is required to identify any human metabolites that do not coelute on LC with previously characterized biotransformation products formed in animals or generated using *in vitro* systems. A related topic centers on our ability to predict circulating human metabolites from *in vitro* data, and an analysis of 17 molecules from the Lilly portfolio showed that in only 41% of cases were the plasma metabolite profiles adequately predicted from *in vitro* data [24]. A somewhat more favorable outcome was reported in a similar study by the Pfizer group [25], in which the success rate in predicting human excretory and circulating metabolite profiles from a panel of 48 compounds was judged to be >70% based on *in vitro* data obtained from pooled human liver microsomes, liver S-9 fraction, and/or human hepatocytes. However, it was noted that the predictability of secondary metabolites was less reliable than that with primary products of biotransformation, and the authors concluded that *in vitro* systems alone cannot mitigate fully the risk of disproportionate circulating metabolites in humans.

While the recommendations contained in the regulatory guidances on MIST likely will remain controversial for some time to come, it is noteworthy that many pharmaceutical companies, for example, Bristol–Myers Squibb [26,27], Lilly [28], and Pfizer [29], have published thoughtful analyses of the topic and, in some cases, have put in place formal strategies for the conduct of drug metabolism studies in support of drug safety evaluation that take into account the issues of disproportionate or unique human drug metabolites. There appears to be general agreement that a “flexible, tiered approach” should be adopted for the characterization and quantitative analysis of stable drug metabolites and that decisions on the need for safety studies on specific human metabolites be based on sound science and well-balanced judgment. Commentaries on MIST from the regulatory bodies themselves would appear to echo this sentiment [30–32].

Underlying many of the criticisms of the MIST guidances discussed above is the fact that relatively few examples exist where a stable drug metabolite has been clearly implicated as the causative agent in the adverse effects observed on dosing with the parent drug. This observation has been rationalized in terms of the normally modest structural changes that accompany mammalian biotransformation reactions, which suggests that most drug metabolites will exhibit off-target effects that are qualitatively similar to those of their respective parents, although quantitative differences can be expected because of changes in certain physicochemical properties, for example, polarity, which influences plasma protein binding and tissue penetration [12,26]. However, exceptions do exist, such as the neurotoxin 1-methyl-4-phenyl-pyridinium (MPP⁺), formed by monoamine oxidase-B (MAO-B)-catalyzed metabolism of the illicit drug impurity 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) [33], the acyl glucuronide conjugate of gemfibrozil, which serves as a mechanism-based inhibitor of CYP2C8 and thereby causes a number of drug interactions [34], and the sulfate conjugate of troglitazone, which has been shown to inhibit the hepatic transport proteins BSEP and OATP and is believed to contribute to cholestatic liver injury in diabetic patients treated with troglitazone [35] (Fig. 7.1). In these examples, the toxicity observed following administration of the respective parent is believed to be due to the stable metabolite

Figure 7.1 Structures of metabolites believed to be responsible for the adverse effects of their respective parent compounds. MPP⁺ is formed as a product of MAO-B-mediated oxidative metabolism, while the acyl glucuronide and sulfate conjugates of gemfibrozil and troglitazone result from the action of UDP glucuronosyltransferase and sulfotransferase enzymes, respectively.

in question. Of course, in certain instances, biotransformation of a drug molecule will result in the formation of a stable metabolite whose structure differs markedly from that of the parent, as may occur on an internal cleavage mediated by oxidative or hydrolytic processes, and the toxicological properties of that metabolite may well be quite distinct from those of the parent, for example, cyanide ion formed on hydrolysis of the naturally occurring glycoside amygdalin (Leatrole) [36]. The reverse situation also can apply, namely, that the toxicity resides in the parent drug but metabolism leads to a nontoxic product because of a significant change in structure–activity relationships (SARs) for the biological targets that mediate the therapeutic effects versus the toxicity. A classic example of the latter scenario is found with terfenadine (Seldane), a potent histamine H₁ antagonist that was marketed for the treatment of seasonal allergies. Although not appreciated at the time of launch in 1985, terfenadine binds avidly to human ether-à-go-go related gene (hERG) (the α -subunit of the cardiac I_{Kr} (potassium-dependent delayed rectifier current) potassium channel), blockade of which leads to delayed ventricular polarization, prolongation of the QTc interval and, in extreme cases, potentially fatal cardiac arrhythmias [37]. In contrast, fexofenadine, the major metabolite of terfenadine in humans and the most abundant drug-related material

Figure 7.2 Metabolism of terfenadine to fexofenadine catalyzed by CYP3A4. This oxidation pathway results in a modest loss of activity at the histamine H1 receptor but in a large decrease in affinity for the hERG channel. Potent inhibitors of CYP3A4, for example, erythromycin and ketoconazole, effectively block the conversion of terfenadine to fexofenadine, and thereby increase exposure to terfenadine to levels that cause cardiotoxicity through prolongation of the QTc interval.

in the systemic circulation following an oral dose, has negligible binding affinity to hERG but retains good antihistamine activity. The conversion of terfenadine to fexofenadine in humans is catalyzed by CYP3A4 [38], and potent inhibitors of this enzyme, such as erythromycin and ketoconazole, block the metabolic “detoxification” process and lead to blood levels of terfenadine at which cardiotoxicity is manifest (Fig. 7.2). Recognition of the molecular basis of this serious drug–drug interaction led to the removal of terfenadine from the market in 1997 and its replacement by the metabolite fexofenadine (Allegra). While this drug interaction attracted widespread attention and had profound consequences for the pharmaceutical industry (introduction of high throughput screens for hERG binding in drug discovery programs), it also underscores the necessity to fully understand, at as early a stage as possible, the spectrum of off-target activities associated not only with the parent drug, but with its major circulating metabolites. This applies particularly to inhibition of the hERG channel (potential for cardiotoxicity) and to the inhibition of human CYP enzymes (potential for drug–drug interactions). While SARs have been relatively well established for hERG inhibition [39], much remains to be learned about those for CYP inhibition, and relatively few studies have examined the contribution of circulating human metabolites to drug–drug interactions that occur at the level of CYP inhibition [40].

7.4 REACTIVE DRUG METABOLITES

As pointed out above, there are relatively few cases where stable drug metabolites are believed to mediate the toxicity of their respective parent compounds. In contrast,

chemically reactive metabolites, most commonly generated via oxidative reactions catalyzed by the cytochrome P450 (CYP) family of enzymes [41], have been implicated in a variety of drug-induced toxicities [5,42,43]. The deleterious effects of these short-lived electrophilic species are thought to arise from their propensity to cause oxidative stress and/or to covalently modify biological macromolecules (primarily proteins and nucleic acids) and thereby alter normal cellular function. For example, covalent adduction of DNA by “hard” electrophiles can lead to mutagenesis, carcinogenesis, and teratogenesis [44], while “soft” electrophiles typically target nucleophilic centers on peptides and proteins and have been implicated in both target organ toxicities (notably those involving the liver [45–47]) and idiosyncratic reactions mediated by the immune system [48–51]. In the area of human pharmaceuticals, most reactive metabolites fall into the category of “soft” electrophiles, the formation of which can be inferred from their *S*-linked conjugates with the tripeptide GSH or through their covalent adducts with proteins which are most effectively detected with the aid of a radiolabeled analog of the drug [1,52]. It is of interest to note that, of the four broad categories of drug-induced toxicity proposed by Park *et al.* [53], reactive metabolites are proposed to play a central role in three of these mechanisms, when they have been associated mainly with hepatotoxicity, skin reactions, and blood dyscrasias [42]. However, it is equally important to point out that not all reactive metabolites are toxic, and the formation of adducts with GSH and proteins is not, *per se*, indicative of a hazardous compound [52]. Nevertheless, an analysis of drugs that have been removed from the market (or labeled with a “black box” warning) because of safety concerns has shown that, next to primary or secondary pharmacology, the major reason was direct organ toxicity, potentially associated with metabolic activation events. This suggests that reactive metabolite formation, while not an accurate predictor of drug toxicity in humans, represents a significant risk factor in drug development.

Growing concerns over the high attrition rates in drug development, and the recognition that toxicity is a major contributing factor, has led most pharmaceutical companies to implement strategies that aim to minimize potential metabolic activation liabilities in their development candidates. In 2004, the Merck group proposed a strategy based on an assessment of the covalent binding properties of lead compounds emerging from drug discovery programs, and outlined a set of decision-making criteria on which to advance lead candidates [54]. Metabolic profiling studies were performed in parallel to the measurements of covalent binding, focusing on the formation of GSH–drug conjugates whose structures provide a rationale for chemical modification to abrogate the formation of reactive metabolites [55]. Updates to the Merck strategy have been published as more practical experience has been gained [56–59], and a number of commentaries have appeared on approaches to minimize metabolic activation in drug discovery programs [60–63]. Much has been made of “toxicophores” or “structural alerts” (structural motifs that have been associated with metabolic activation to reactive electrophiles) [64], and Kalgutkar *et al.* [65] have published a comprehensive listing of functional groups that have been shown, in certain molecules, to undergo bioactivation to electrophilic intermediates. While helpful to the medicinal chemist engaged in drug design, it should be borne in mind that the presence of a toxicophore in a given drug structure is relevant only when that functional group is accessible to the appropriate activating enzyme in a biological milieu; in that context, it is important to assess experimentally whether metabolism of a promising drug candidate indeed occurs at the functionality of concern before rejecting the molecule from consideration. In some

examples, the toxicophore may be as simple as an electron-rich benzene ring, as was the case in the lead candidate in a cannabinoid-1 receptor (CB-1 R) inverse agonist program (compound **1**, Table 7.1), which underwent sequential metabolic oxidations to afford reactive arene oxide and *ortho*-quinone intermediates that were captured in the form of their GSH adducts [66,67]. Labeling of **1** with tritium demonstrated that this compound gave rise to very high levels of protein covalent binding (~3900 pmol-equiv/mg protein) in both rat and human liver microsomal preparations, and a series of analogs were prepared with the goal of reducing this bioactivation liability, while simultaneously retaining (or enhancing) the favorable pharmacological and pharmacokinetic characteristics of the lead structure. The modifications centered on reducing the electron density on the offending aromatic ring, through introduction of fluorine atoms (**2**), replacement of the phenoxy substituent by a 2-pyridyloxy (**3**) or 5-CF₃-2-pyridyloxy group (**4**), each of which led to progressively lower levels of covalent binding *in vitro*. The final compound in the series (**5**), which incorporated a nitrile substituent in the distal phenyl ring, exhibited a very low level of covalent binding (27 pmol-equiv/mg protein), had excellent Pharmacokinetic (PK) properties in rats and was almost an order of magnitude more potent at the CB-1 R than the initial lead. On the basis of these attributes, compound **5** was advanced into development, and became Taranabant, Merck's candidate CB-1 R inverse agonist for the treatment of metabolic syndrome [68].

In those situations, where electrophilic metabolites are highly reactive, alkylation of the apoprotein and/or prosthetic heme moiety of the responsible CYP enzyme may occur, resulting in mechanism-based inactivation of the enzyme. This phenomenon, which manifests as a time-dependent loss of enzyme activity *in vitro* (and often is the first indication that a new drug candidate is subject to metabolic activation), has potentially important safety implications for clinical drug–drug interactions with cosubstrates of the P450 isoform in question, and molecules with this undesirable property normally are “screened out” at the discovery stage [69–72]. Similarly, metabolism of certain functional groups, notably the methylenedioxyphenyl moiety and substituted aliphatic amines, affords electron-deficient intermediates that coordinate tightly to the Fe^{II} oxidation state of CYP heme and form inhibitory “metabolic intermediate” (MI) complexes that can be detected spectrophotometrically through their characteristic λ_{max} at 455 nm [71,72]. An example of a lead optimization program which focused on the removal of MI complex formation from an important lead molecule was reported by Tang *et al.* [73] and illustrates how an early understanding of potential metabolic liabilities in a given structural class can be key in guiding medicinal chemistry efforts. *In vitro* investigation of the melanocortin-4 receptor (MC4R) agonist **6** (Fig. 7.3), being explored for a weight-loss indication, showed that this compound inhibited CYP3A enzyme activity in nicotinamide adenine dinucleotide phosphate (NADPH)-fortified rat and human liver microsomal preparations and yielded a typical MI complex spectrum when incubated with recombinant CYP3A4 (Fig. 7.4). Since compound **6** contained an aliphatic amine moiety, it was hypothesized that sequential CYP-mediated N-oxidation afforded the corresponding hydroxylamine and nitroso derivatives and that the latter species coordinated with P450 heme iron to generate the observed MI complex. This hypothesis was tested by *in vitro* trapping experiments with cyanide ion [74], which resulted in the identification by LC-MS/MS of a cyano adduct whose formation could be rationalized by invoking capture, not of the nitroso species per se, but of the tautomeric oxime, followed by a further two-electron oxidation step of the adduct to give the final

Figure 7.3 Structure of a lead MC4R agonist **6** and the proposed mechanism by which it caused time-dependent inhibition (TDI) of CYP3A4. Trapping experiments with CN^- , which afforded the indicated cyano-nitroso species, led to design of **7**, in which the methyl substituent α - to the primary amine introduced sufficient steric hindrance to suppress oxidation at this center to the inhibitory nitroso metabolite.

product (Fig. 7.3). These findings led to the design of compound **7**, in which a methyl group was introduced α - to the primary amine functionality in order to sterically hinder the offending N-oxidation reaction. This simple structural modification afforded a compound with greatly diminished MI complex formation and CYP3A inhibitory properties, thereby provided a drug candidate with an improved safety profile in terms of potential drug–drug interaction liabilities [73].

Figure 7.4 Spectrophotometric detection of the MI complex formed in incubations of **6** with recombinant CYP3A4. The absorbance increased with increasing incubation time (0, 5, and 10 min) and decreased on addition of potassium ferricyanide which converts heme iron to the Fe^{III} oxidation state and dissociates the MI complex. *Source:* Adapted from Ref. 73.

In the foregoing examples, it will be evident that a number of analytical techniques are employed in the detection of reactive metabolite formation, for example, UV spectroscopy for MI complexes, use of radiotracers for metabolic profiling and covalent binding studies, and *in vitro* nucleophilic trapping experiments with structural analysis by LC-MS/MS or NMR. By far, the most widely used nucleophile for the latter purpose is GSH, due both to its physiological role as an endogenous scavenger of potentially damaging electrophiles and to the favorable mass spectrometric characteristics of the resulting drug–GSH adducts under a variety of ionization conditions [75–78]. In recent years, a variety of LC-MS/MS-based methods have been reported for screening drug candidates for reactive metabolite formation *in vitro*, based on trapping experiments with GSH itself, or analogs such as GSH ethyl ester [79], quaternary ammonium derivatives of GSH [80], and stable isotope-labeled ($^{13}\text{C}_2$ and ^{15}N) GSH [81,82]. An interesting variation on this theme is the use of γ -glutamylcysteinyllysine (γ -GSK) as a bifunctional trapping agent, which has been shown to capture both “soft” and “hard” electrophiles [83]. The advent of LC-MS/MS systems with rapid scanning mass analyzers (e.g., time-of-flight) capable of operating under conditions of high mass resolution has provided an additional dimension in screening technology, based on elemental composition data and the technique of mass defect filtering [82,84–87]. Despite the power of mass spectrometry-based methods for the detection

and identification of GSH adducts, such approaches do not yield reliable information of a quantitative nature in the absence of authentic standards of the conjugates of interest because of differences (sometimes quite marked) in the ionization efficiency of individual adducts. Attempts have been made to address this problem by the use of ^3H - or ^{35}S -labeled GSH as trapping agents, with radiometric analysis of the products [88,89] or dansyl GSH followed by fluorometric analysis [90], both of which can provide quantitative information in the absence of synthetic reference materials. It is generally assumed that the reaction of GSH with reactive drug metabolites *in vitro* is predominantly a chemical process, although in certain cases, glutathione-S-transferase-mediated conjugation may contribute to product formation; analogs of GSH (or GSH surrogates, e.g., *N*-acetylcysteine) would not be appropriate for quantitative purposes in such situations since these nucleophiles do not serve as substrates for the transferase enzymes. While efforts have been made by some investigators (with limited success) to correlate thiol formation in liver preparations *in vitro* with measures of covalent binding *in vivo* and hepatotoxicity in animals or humans [91,92], it would seem that the greater value of GSH trapping experiments lies in the structural information that can be inferred on the identities of the reactive electrophiles being captured. When this insight is provided at a sufficiently early stage in drug discovery programs, rational structural changes can be made in lead compounds to block, or suppress, pathways of bioactivation, thereby minimizing the potential for reactive metabolite-mediated toxicities [93]. Although the foregoing discussion has focused on the detection of reactive metabolites using appropriate *in vitro* systems, extension of these studies to *in vivo* investigations typically rely on the collection of bile from animals dosed with the NCE of interest, and the identification of GSH adducts present in that fluid. Alternatively, the excretion of *N*-acetylcysteine (mercapturic acid) conjugates in urine, either of animals or human subjects, provides an insight into bioactivation processes occurring *in vivo* [77].

In assessing the potential risk to humans associated with a development candidate that has been demonstrated to undergo metabolism to reactive intermediates, a number of considerations need to be borne in mind, for example, the chemical tractability of the structural series from which the candidate was selected, the availability of existing treatments for the target disease, the severity of that disease (life-threatening or otherwise), the anticipated daily dose (and hence body burden of reactive metabolites), the expected duration of therapy (which will determine long-term exposure to reactive metabolites), the intended clinical population (adult vs children), and the balance between bioactivation and detoxification pathways *in vivo* [54,93]. It also should be recognized that chemically reactive intermediates will exhibit a large range of reactivities in a biological environment, which will influence their ability to migrate from sites of formation within the cell to other organelles, or even to distant organs. For example, the diquinonemethide metabolite of raloxifene, a selective estrogen receptor modulator, has been shown to have a half-life of <1 s in aqueous phosphate buffer at 5°C , while an *ortho*-quinone metabolite of the same drug exhibited a half-life of 69 min in the same medium at 37°C [94] (Fig. 7.5). Thus, while the majority of electrophilic drug metabolites have biological lifetimes that are too short to allow for their detection and characterization as the native species, a subset of these products will have relatively low chemical reactivities and therefore will be detectable in the circulation and excreta. A prominent example of the latter group is the class of acyl glucuronide conjugates, which are formed from many carboxylic acid-containing xenobiotics and frequently

Figure 7.5 Structures of raloxifene and two quinoid metabolites with markedly different stabilities in aqueous phosphate buffer.

circulate in the bloodstream or are eliminated in bile or urine [95–98]. Owing to the propensity of these ester-linked conjugates to undergo intramolecular rearrangement reactions with resulting exposure of α -hydroxy-aldehydes from the sugar ring, they possess the ability to form stable covalent adducts to proteins. Direct acylation of proteins also can occur with acyl glucuronides (as is the case with the much more reactive acyl-coenzyme A thioesters, which usually do not escape the cell). In light of their ability to covalently modify proteins, concerns have been raised over the safety of acyl glucuronides as a structural class. Specifically, it has been noted that acyl glucuronide conjugates may be concentrated in hepatocytes and the biliary tree due to vectorial transport by export pumps, where they may bind selectively to canalicular membrane proteins [95]. Such concerns have been heightened by the fact that a relatively large proportion of drug withdrawals because of hepatotoxicity have involved carboxylic acid derivatives that yield acyl glucuronide conjugates [99]. Despite the fact that more recent investigations of some of these agents (e.g., zomepirac and tolmetin [100]) have

revealed pathways of bioactivation that involve metabolic *oxidations*, there has been a tendency to associate acyl glucuronide formation with a risk of adverse drug reactions, notably liver injury. Such a broad generalization seems inappropriate, since many carboxylic-acid-containing therapeutic agents that give rise to acyl glucuronides have a favorable safety profile, yet acyl glucuronide conjugates are referred to collectively in the FDA guidance as *toxic molecules* [3]. While it may be possible to assess the intrinsic reactivity of a particular acyl glucuronide *in vitro*, for example, by monitoring rates of intramolecular migration or direct acylation of model nucleophiles, there currently is a lack of consensus on the value of such information for risk assessment purposes. It is perhaps more appropriate, therefore, to treat this class of conjugates in the same fashion as stable drug metabolites, where exposure margins in animal species are taken as indices of safety in humans.

Unlike the situation with stable drug metabolites, there are no regulatory guidelines that deal specifically with chemically reactive metabolites, although the European Medicines Agency acknowledges that drug-induced hepatotoxicity may, in some cases, be mediated by reactive metabolites [101]. The lack of a direct correlation between the formation of electrophilic drug metabolites and drug-induced toxicity has confounded the interpretation of data on metabolic activation and covalent binding to proteins and underscores our general lack of understanding of the molecular mechanisms by which reactive intermediates damage cells [52]. While studies aimed at correlating the extent of covalent binding *in vitro* of hepatotoxic versus nonhepatotoxic drugs have yielded conflicting results [102,103], experimental protocols based on the use of human hepatocytes that incorporate estimates of dose (or body burden of reactive metabolites) have shown some promise as predictors of hepatotoxic potential [92,104–106]. It has been suggested that, for practical purposes, an estimated reactive metabolite body burden in humans of <10 mg/day may represent an acceptable risk [7,8], although this proposed upper limit probably will be highly dependent on the nature of the reactive metabolite in question, the identities of its macromolecular targets, and individual host susceptibility factors. Currently, very little is known about the protein targets of reactive drug metabolites and even less about those structural modifications induced by protein alkylation that have toxicological consequences [107]. Advances in the techniques of proteomics mass spectrometry have made it possible to address the structural issues [108], but analysis of the hundreds (or thousands) of proteins that are subject to chemical modification by reactive drug metabolites presents a formidable challenge. For these reasons, it seems prudent, in the context of drug discovery programs, to incorporate a formal assessment of metabolic activation of NCEs at an early stage (e.g., during lead optimization) with a view to minimizing, through appropriate structural modifications, the risk of downstream adverse drug reactions mediated by chemically reactive metabolites. As noted above, most major pharmaceutical companies now subscribe to this general approach, although individual corporate strategies differ in terms of the timing of such studies and their experimental design.

In considering the role of reactive intermediates in drug toxicity, it should be pointed out that some important therapeutic agents actually elicit their pharmacological effects through chemically reactive metabolites or products of chemical rearrangement that covalently modify their biological targets. Thus, the thieno-tetrahydropyridine antiplatelet agents (e.g., ticlopidine and clopidogrel [109]) and the proton pump inhibitors (e.g., omeprazole, esomeprazole, and lansoprazole [110]) undergo conversion *in vivo* to reactive sulfenic acid species which, in turn, form disulfide

Figure 7.6 Cytochrome P450-mediated metabolism of clopidogrel to an acyclic sulfenic acid that binds covalently to an active site cysteine -SH group on the platelet P2Y₁₂ receptor.

linkages with active site -SH groups of their respective targets (P2Y₁₂ receptor on the surface of blood platelets and H⁺/K⁺ adenosine triphosphatase (ATPase) at the secretory surface of the gastric parietal cell). As an example, the mechanism by which clopidogrel (Plavix) inactivates its target receptor is depicted in Fig. 7.6. The relative safety of these widely used drugs probably is related to the high degree of specificity with which their active moieties interact with their target proteins, and the fact that the covalent linkage in each case is a disulfide bond, which can be reduced over time to regenerate the native protein. Interestingly, this concept of specific, reversible covalent modification of proteins has been advanced as a discrete strategy in the design of a new generation of potent, relatively long-acting therapeutic agents with low potential for toxicity [111].

Finally, reactive metabolites need to be taken into consideration when assessing the genetic safety of new pharmaceuticals, given the well-established role of drug metabolism in the genotoxicity and carcinogenicity of chemicals [44]. Traditionally, the potential of a new drug candidate and its mammalian metabolites to cause genetic toxicity is evaluated during the early stages of drug development through a combination of *in vitro* studies (e.g., using liver microsomal preparations from Aroclor-pretreated rats to enhance the production of metabolites) and *in vivo* assays (e.g., micronucleus assay in rat or mouse) [2]. Only in those cases where metabolism studies have identified a “unique” human metabolite, or where the structure of a metabolite of the

drug candidate of interest contains a genotoxicity “alert,” are follow-up studies normally performed with the metabolite per se. For example, when a human metabolite is not generated in rats or mice, assessment of its genotoxic potential could include the use of an alternative or optimized *in vitro* metabolic activation system or direct testing of the isolated or synthesized metabolite [112]. In recent years, a number of *in silico* approaches, involving expert systems or statistical modeling techniques, have been applied to predict human genotoxicity risk [113], and these have been adopted by both pharmaceutical companies and regulatory agencies as a screen for potentially problematic drug candidates, their known metabolites, and synthetic impurities in the active pharmaceutical ingredient. In situations where a drug candidate yields a human metabolite that tests positive in one or more assay in a genotoxicity panel, due consideration needs to be given to issues such as the intended therapeutic indication of the parent compound, the projected dose and duration of treatment, and the likely body burden of the genotoxic intermediate, in developing an overall strategy for risk assessment [114].

7.5 CONCLUSIONS

On the basis of the above discussion and the examples presented in this chapter, it will be evident that drug metabolism as a discipline plays a unique role within the pharmaceutical industry, in that it serves to bridge drug discovery projects to both preclinical and clinical drug development. In particular, a sound knowledge of the pharmacokinetic, metabolic, and dispositional characteristics of NCEs in animals, coupled with information on known or suspected human metabolites, represents a critical body of data for validating the choice of the animal species selected for the preclinical toxicology program. Evidence for the formation of chemically reactive metabolites has clear implications for the medicinal chemist with regard to logical directions for lead optimization, while at the clinical level, information on exposure margins for circulating stable metabolites dictates the need, if any, for further safety evaluation of specific biotransformation products. For all these reasons, drug metabolism studies represent an integral component of today’s drug safety assessment programs.

Looking to the future, one can anticipate that current advances in the fields of genomics, proteomics, and metabolomics will combine to provide a detailed insight into the numerous mechanisms by which foreign compounds elicit their specific adverse effects, and thereby provide a link between chemical structure and molecular toxicology. New tools will emerge at the drug metabolism/safety assessment interface, for example, the use of genetically engineered mouse models that express human P450 enzymes to address issues related to species differences in metabolism and toxicity [115,116]. An improved understanding of the role of redox-sensitive signaling pathways, for example, Kelch-like ECH-associated protein 1 (Keap1)-Nrf2-ARE [117], in protecting against the potentially deleterious effects of reactive drug metabolites, could lead to the development of *in vitro* screens for chemical stress and idiosyncratic drug toxicity, and improved biomarkers of cellular damage due to exposure to electrophilic drug metabolites likely will emerge, for example, induction of heme oxygenase-1 in human hepatocytes [118]. The intriguing question of what makes one human subject more susceptible to the toxic effects of a drug/drug metabolite than hundreds (or thousands) of other patients may be answered, at least in part, by genetic determinants

in the immune system, as has been shown to be the case with abacavir hypersensitivity which is strongly correlated with the presence of the human leukocyte antigen (HLA)-B*5701 [119]. It seems inevitable that the Holy Grail of predictive toxicology will emerge from close partnerships between drug metabolism and industrial safety assessment—an exciting prospect indeed!

8.1 SUMMARY

Determination of the nature and the rates of any active processes that are involved in the absorption, distribution, metabolism, and elimination (ADME) of drug candidates is a primary goal of drug discovery. These processes include metabolism and active transport. Metabolism entails the (usually) irreversible enzyme-mediated conversion of the compound to a different form. Active transport entails the movement of an unchanged compound, mediated by a transporter protein, across a biological membrane (frequently the plasma membrane). Within drug discovery, *in vitro*, *in situ*, and *in vivo* methods for estimating human drug metabolism and transport are becoming increasingly supplemented by a wide range of *in silico* methods aimed at reducing costs, reducing animal usage, and increasing throughput of compound screening.

These active processes are potentially subject to drug–drug interactions, whereby one drug (or, in general, any xenobiotic) alters the rate of metabolism or transport of a second xenobiotic *in vivo*, leading to changes in plasma and target-site concentrations of the affected drugs. Several mechanisms for such interactions exist, including reversible or irreversible inhibition of transporters and enzymes and increases in their expression mediated by activation of nuclear receptor proteins. *In silico* methods are being developed to predict these effects, to reduce the cost and time burden of experimental screening and to mitigate the likelihood that undetected drug–drug interactions with undesirable consequences could compromise otherwise promising drug candidates.

Following a brief review of drug metabolism and drug–drug interactions (Section 8.2), we present a high level view of some of the areas in which *in silico* modeling can contribute to the quantitative or qualitative understanding and prediction of drug metabolism and drug–drug interactions (Sections 8.2.1 and 8.2.2). We then discuss some of the available *in silico* approaches to these problems (Section 8.3). We start our discussion with methods that just depend on descriptors calculated from compound structure (Section 8.3.1), go on to discuss more complex models that use compound structure more explicitly (Section 8.3.2), then discuss approaches that try to model in detail the interaction between compound and protein (Section 8.3.3). Following this, we discuss in some detail a number of specific application areas in each of which one, or more, of the previously described methods have been used (Sections 8.4.1–8.4.3). These application areas include prediction of the rate of metabolism of a compound; determination of the substrate and/or inhibitor specificity of enzyme and transporter isoforms; and activation of the pregnane X receptor (PXR), a nuclear receptor which is known to be involved in the xenobiotic-mediated induction of a number of drug-metabolizing enzymes and transporters.

The approaches discussed up to this point do not permit the understanding of the interactions between different active processes *in vivo*; we, therefore, then (Section 8.4.5) discuss physiologically based modeling, which, in principle, allows the creation of an integrated model of compound pharmacokinetics that allows the modeling and understanding of all relevant physiological processes involved in drug metabolism and interactions. We finish with a discussion of some practical aspects of applying *in silico* methods in drug discovery (Section 8.5) and our conclusions on the topic (Section 8.6). Having such a large and diverse subject matter to cover, we realize that we cannot be comprehensive and have therefore cited several relevant recent papers for readers to follow-up.

8.2 INTRODUCTION

Drugs and other xenobiotics are potentially subject to metabolic transformation by enzymes and enzyme systems located in the liver, intestine, and other organs. Metabolism of drugs usually leads to reduction, or total loss, of their therapeutic effect, in which case the rate of metabolism can be a prime determinant of their *in vivo* therapeutic utility. Metabolism can sometimes generate toxic metabolites [1], thus contributing to the toxicity of a drug, or to active metabolites, contributing to its therapeutic effect [2]. The latter effect can be deliberately harnessed in the production of prodrugs that have, for example, favorable absorption properties but require metabolism to generate the therapeutically active compound [3,4]. The bulk of xenobiotic metabolism is performed by the cytochrome P450 (CYP) superfamily of enzymes [5], which tend to transform compounds into more polar compounds. These metabolites can be either eliminated directly or become subject to further metabolism [6].

Until relatively recently, the role of active transport in the disposition of drugs had been poorly studied in comparison to the effort put into investigating and understanding drug transport. The effects of phosphoglycoprotein (PGP) (MDR1/ABCB1) and MRP1 (ABCC1) on drug disposition had originally been observed because of their roles in the development of multidrug resistance in cancer cells [7], and there was an appreciation

of their potential in inhibiting drug uptake from the gastrointestinal (GI) tract [8] and from the blood across the blood–brain barrier [9]. Some compounds must be transported into the interior of the hepatocyte to reach the metabolizing enzymes and some compounds can be transported out of the hepatocyte into the bile [10]; the rate of transport can have an effect on the overall rate of removal from the bloodstream [11]. Transporter proteins also affect the absorption of a compound from the gut—some help compound uptake and some pump compound back into the gut lumen [12]—and hence also have an effect on the overall extent of metabolism. Transporter polymorphism can have a significant effect on pharmacokinetics [13–15].

The activity of the metabolizing enzymes and transporter proteins can be induced by a range of drugs or environmental factors and can be inhibited by a range of drugs or foodstuffs [16]. Xenobiotic concentration in plasma or tissues can significantly be affected by interactions with other compounds and can vary by an order of magnitude or more [17]. This can lead to unwanted behavior: either a lack of efficacy at a standard dose caused by an increase in overall clearance or toxic effects caused by a decrease in overall clearance. For a compound with a narrow therapeutic window—when the effective dose is close to the toxic dose—this is particularly significant. Assessment of the potential of a clinical candidate to participate in drug–drug interactions is an integral part of review by regulatory bodies [17]. Compounds that are found to participate in drug–drug interactions must undergo *in vivo* tests to determine the extent of any *in vivo* drug–drug interactions [18].

Inhibition of CYP3A4 has been a particular concern in drug development, and pharmacokinetic changes following CYP3A4 inhibition have led to the withdrawal from market of a number of compounds. Terfenadine, cisapride, and astemizole are CYP3A4 substrates that, in excess, can cause cardiac arrhythmias. If their concentrations rise—due to the inhibition of their metabolism—adverse, potentially fatal, effects can ensue. These side effects on coadministration with CYP3A4 inhibitors led to their withdrawal. The significance of CYP3A4 inhibition relates to two factors. First is the preponderance of this isoform in the metabolism of many drugs and drug-like compounds. Second is that its substrates are often lipophilic (as discussed further below), which increases the likelihood of unwanted off-target interactions *in vivo*, such as those with the human ether-a-go-go-related gene (hERG) protein [19,20] that caused the arrhythmias noted above. The postmarketing discovery of enzyme inhibition has also led to the withdrawal of mibefradil, an inhibitor of CYP3A4 and PGP [21].

Induction of drug-metabolizing enzymes is less dangerous, insofar as the consequence is reduced concentrations of the substrate(s) of the induced enzyme(s), but this does raise the possibility of therapeutic failure of such substrates, with potentially serious consequences. A common mechanism for CYP induction is binding of ligand to nuclear receptors that regulate transcription, which alters the expression of the CYP genes [22]. This means that potential CYP inducers can be identified as potential binders to the relevant nuclear receptors. As examples, plasma levels of CYP3A4 substrates—for instance, oral contraceptives, triazolam, and midazolam—can be reduced by coadministration of CYP3A4 inducers [22–24], leading to a lack of efficacy at standard doses.

There are a number of transporter-based interactions documented in the literature: for instance, an increase in repaglinide plasma concentration following atorvastatin dosing due to an inhibition of OATP1B1 [25], an increase in plasma concentration of rosuvastatin following cyclosporin dosing due to the same effect [26], and an increase

in atorvastatin plasma concentration following rifampin dosing [27,28]. Transporter inhibition does not yet seem to have been as serious as metabolic inhibition, but the capacity for clinically significant changes in pharmacokinetics exists.

Just in this brief discussion of the biochemistry and physiology that affects xenobiotic metabolism, we find some questions that must be answered—qualitatively or quantitatively—during drug discovery, to produce high quality development candidates:

1. The overall rate of metabolism, which affects the tissue concentrations reached after administration, and consequent duration of action of the drug;
2. The identity of major metabolites along with knowledge of whether, or not, they are toxic and/or therapeutically active
3. The enzyme/enzymes that is/are responsible for the majority of metabolism and, where more than one enzyme is involved, the relative proportions of metabolism via each enzyme. This determines the potential for
 - a. Differences in metabolism between different individuals of the target population
 - b. Effects of polymorphisms in drug-metabolizing enzymes
 - c. Inducibility of drug metabolism, and the identities of potential inducers
 - d. Inhibitability of drug metabolism, and the identities of potential inhibitors
4. Potential effects on metabolism of other drugs that could be coadministered, whether by induction or inhibition of drug-metabolizing enzymes.

Furthermore, with the increasing recognition of the importance of active transport in affecting the disposition and elimination of drugs, there is a corresponding increase in emphasis being given to determining the analogous properties (excluding 2) relevant to drug transport in the liver, kidneys, intestines, and other tissues.

8.2.1 Why Is *In Silico* Modeling Necessary?

All the above properties can be determined, in principle, by appropriate *in vitro* assay. But a liability in any one property could cause costly clinical failure of a candidate, so there is a consequent drive to determine these properties as early as possible within drug discovery. This leads to increasing costs and compound requirements in lead generation and optimization, as additional assays are developed and used to inform the discovery process. This generates competition for resources in lead identification and lead optimization that requires careful prioritization for successful outcomes at affordable costs. Improvements in assay miniaturization and throughput [29] have helped offset these costs, but there is still a potentially crucial role for *in silico* modeling to inform prioritization of assays, and hence to ease the competition for resources throughout drug discovery. First, predictive models for *in vitro* assay endpoints can be used to reduce the number of assays to be performed and/or to increase the number of compounds—whether real or virtual—that can be screened. Second, models can be used to extrapolate from *in vitro* assay endpoints (or predictions thereof) to predict *in vivo* pharmacokinetics. A variety of *in silico* techniques are used across the entire range of ADME, toxicity, pharmacology, and physicochemical properties [30–40], of which applications relating specifically to drug metabolism and drug–drug interactions [17,41–47] are a subset.

8.2.2 Problems for *In Silico* Modeling

This leaves us with a number of problems that could be addressed by *in silico* modeling.

1. Predict the total rate of metabolism of a compound.
2. Predict whether a compound is metabolized by a given enzyme, or enzyme isoform, and the rate of such metabolism. One difficulty is that the enzymes, such as CYPs and uridine 5'-diphosphoglucuronic acid (UDPGA) glucuronosyl transferases (UGT), that control a significant fraction of drug metabolism are promiscuous, metabolizing a wide range of substrates. If interactions with a given metabolizing enzyme are predicted, predict the kinetics of transformation, and also the metabolite or metabolites formed.
3. Predict whether a compound is transported by a given transporter and the rate of such transport. Just like the metabolizing enzymes, the transporters are promiscuous proteins that interact with a variety of drugs, and any interaction with a transporter is a potential source for drug–drug interactions with compounds that affect that transporter. If interactions with a given transporter are predicted, this can give some idea of the population variability that may be expected.
4. Predict whether a compound inhibits metabolism or transport of itself or other compounds. Is the compound likely to prevent the metabolism or transport of other compounds? Does it affect important enzymes, risking interactions with many other drugs, or does it just affect a relatively insignificant enzyme?
5. Predict whether a compound induces metabolizing enzymes or transporters. Does the compound bind to a nuclear receptor, causing increased expression of CYP or transporter protein? Which enzymes does it induce; are they important, or relatively insignificant in the metabolism of the drug, or of coadministered drugs?
6. Predict or model, quantitatively, total *in vivo* clearance or concentration time profiles. What effects do metabolism and transport have on the compound's pharmacokinetics, and how do they interact with absorption and distribution. If one can model *in vivo* metabolism and transport to the extent of individual enzymes, one could begin to understand the compound's susceptibility to population variability and enzyme induction or inhibition. A model of this class is a useful tool: one can ask the questions “by how much do I have to inhibit metabolism to increase plasma concentration of my drug or a probe substrate by x -fold?” or “by how much do I have to induce metabolism to decrease plasma concentration of my drug or a probe substrate x -fold?,” where the value of x can be dependent on the drug's therapeutic window. It is possible to begin to understand the true *in vivo* significance of an interaction discovered *in vitro*.
7. Predict or model, quantitatively, inhibition or induction effects due to the dosed compound or caused by a coadministered drug. With knowledge of effective and toxic concentrations, a model of this class directly addresses changes in the therapeutic window of the compound or of a coadministered drug. Such a model also aids in the design of *in vivo* clinical studies that examine an interaction in detail. One may, perhaps, attempt full prediction from *in vitro* data, or one may take the single-compound pharmacokinetics as given and just attempt to model the compound–compound interaction.

8.3 TOOLS

In this section, we discuss in some detail the different *in silico* approaches to drug metabolism and drug–drug interaction. Generally, we must consider compound interactions with varying promiscuous proteins, whether transporters, metabolizing enzymes, or nuclear receptors. Given this similarity among the different problems, we look at each modeling approach in turn and discuss some advantages and disadvantages of the methods.

8.3.1 Compound Descriptor Methods

A compound can be characterized by a set of molecular descriptors that are classed according to the dimension of the chemical formula used to derive them. One-dimensional descriptors are calculated from the empirical formula and include quantities such as the molecular weight and atom counts. Two-dimensional descriptors come from the planar projection of the chemical structure and include, for example, the number of hydrogen bond donors and acceptors. Finally, the three-dimensional structure of the compound gives rise to three-dimensional descriptors such as charge distribution parameters like the dipole and quadrupole moments [48]. These molecular descriptors form the basis of a quantitative structure–activity relation (QSAR), which relates these molecular descriptors with a specific activity, such as metabolic rate or protein binding affinity, for a training set of compounds [39,49,50]. A huge number of molecular descriptors can be calculated for each compound [48]. However, sensitivity analysis can identify those descriptors having greatest influence over the structure–activity relationship, and restricting the descriptors to this select group helps prevent over-fitting to the compound training set. The major advantage of using compound descriptor methods to predict enzyme metabolism/inhibition is that structural knowledge of the active site is not required so this method can be used to predict enzyme activity when the enzyme structure is unknown.

8.3.2 Compound Structure Methods

The following methods utilize the compound geometry: either the three-dimensional structure or its two-dimensional projection onto a plane. The geometry provides a structural understanding of binding into an active site and we therefore expect compound structure methods to be superior to methods based purely on compound descriptors (Section 8.3.1). Furthermore, as with compound descriptor methods, compound structure-based methods do not utilize the protein structure and can therefore be used when the protein structure is unknown [51–55].

8.3.2.1 Pharmacophore Methods. A pharmacophore is the collection of the most important structural features relevant for a given biological activity from a series of molecules with a similar mechanism of action [56]. Pharmacophore features are, for example, hydrogen bond donors, hydrogen bond acceptors, acidic centers (centers with a negative charge at neutral pH), hydrophobic regions, and aromatic rings [57]. The set of features with their corresponding positions within the molecule then define the pharmacophore. By comparing a set of known enzyme substrates to a set of known

nonsubstrates, the common set of pharmacophore features required for binding to the enzyme active site can be identified. This method can therefore classify other compounds as being substrates or nonsubstrates, depending on whether they contain the same pharmacophore features. However, it will not predict the strength of binding to the enzyme active site and so cannot differentiate between compounds of the same class.

8.3.2.2 Comparative Molecular Field Analysis. Comparative molecular field analysis (CoMFA) is a particular three-dimensional QSAR technique. It requires that a training set of compounds are all aligned, according to some rule, within a three-dimensional grid. The steric and electrostatic fields are calculated for each compound at each point on the grid, which are then correlated with the compound activity. CoMFA is a widely used method in drug discovery, but its success is sensitive to the molecular alignment step. By aligning the compounds, the assumption is made that all compounds have the same orientation in the active site. In reality, however, different compounds will bind to the active site in different orientations, perhaps even several orientations for a given compound [58].

8.3.2.3 Comparative Molecular Similarity Indices Analysis. Comparative molecular similarity indices analysis (CoMSIA) is another three-dimensional QSAR technique where molecules are aligned on a grid and the steric and electrostatic fields calculated [59]. However, CoMSIA is considered superior to CoMFA as the hydrogen bond donor, hydrogen bond acceptor, and hydrophobic fields are also taken into account. At each grid point, these interaction fields are converted to a similarity index [60], which is the property that is correlated with the compound activity. The steric and electrostatic fields, given by the Lennard–Jones and Coulombic potential, respectively, can be excessively large for grid points close to atoms of the compound. The Gaussian function of the similarity index can be designed to moderate this dominant behavior, ultimately resulting in greater predictive accuracy [61].

8.3.3 Protein Structure Methods

The following methods require the three-dimensional structure of the protein, which restricts these methods to systems where this is known, or at least predicted using protein homology models [62]. Since the proteins typically contain several thousands of atoms, these methods are computationally expensive and are not high throughput. However, this disadvantage is somewhat offset since these methods can reveal the exact nature of binding into the active site of an enzyme.

8.3.3.1 Molecular Dynamics. A molecular dynamics simulation provides an atomistic view of enzyme–substrate binding over time. It can capture the different orientations and conformations of the compound in the active site, and the role of solvent molecules if they are included in the simulation too [63]. The accuracy of the simulations depend on the classical force field used to model the interactions between compound and enzyme, which may require parameterizing to higher level quantum calculations. Add this to the already computationally intensive molecular dynamics simulation and it is clear that this method cannot currently be used as a general screening tool in drug discovery.

8.3.3.2 Docking. As the name suggests the compound is docked into the binding site of the enzyme. Each atom pair between the ligand and the enzyme is considered, the separation between the two atoms calculated, and the result converted into an atom-pair potential according to a scoring function. The total binding potential is the sum of the potential energies across all atom pairs. Where entropic and solvation effects have been incorporated into the scoring function, the free energy of binding is obtained [64,65]. However, knowledge-based atom-pair potentials are parameterized on selected sets of ligand–protein structures and may not predict well outside this domain [64].

8.4 APPLICATIONS

Here, we present a variety of examples where *in silico* methods have been used to characterize substrates of CYP, UDP-glucuronosyltransferase, and the PXR according to the different problems that are outlined in Section 8.2.2.

8.4.1 Prediction of the Rate of Metabolism

We start with prediction of overall rate of metabolism, not because it is one of the easiest to address by *in silico* modeling—far from it—but because it is a fundamental property that can significantly affect the likelihood of its progression in drug discovery. Consequently, the *in vitro* determination of metabolic rate (using isolated hepatocytes, or subcellular fractions such as microsomes or S9) is a routine screen utilized in lead optimization, or even lead identification, during drug discovery. Even modest drug discovery programs can result in large numbers of compounds being screened for this property [66]. Consequently, any contribution that *in silico* modeling can make to reduce the need for *in vitro* screening is potentially valuable.

The problem has been studied since the early days of QSAR modeling. For example, Hansch *et al.* [67] developed linear regression models for oxidative deamination of aliphatic amines and benzylamines by a variety of *in vitro* systems (purified amine oxidases, liver extracts, and beef liver mitochondria), for glucuronide formation of benzoic acids and aliphatic alcohols in the rabbit *in vivo* and for hippuric acid formation, also in the rabbit *in vivo*. The models they developed were for small series (7–30 compounds) of closely related, relatively simple compounds, having calculated $\log P$ s in the range 0.7–3.5. They considered hydrophilic/hydrophobic nature, hydrogen bonding capability, polarization, dipole moment, molar volume, pK_a , and electronic and steric properties. In essence, they found that the logarithm of the rate of metabolism (MR) was a parabolic function of calculated $\log P$, of the general form:

$$\log(\text{MR}) = -a \cdot \log P^2 + b \cdot \log P + c$$

with, for a small number of cases, a contributing term from the Taft intramolecular steric substituent coefficient, E_s . These relationships had correlation coefficients between 0.8 and 0.95 on the training set, thus explaining between 64% and 90% of the variance of the training sets. Now, these relationships are unlikely to generalize beyond the training sets (because of the relatively large ratio of fitted parameters to compounds), and are not necessarily applicable to larger, more complex drugs and drug leads, but they did provide valuable insight into important characteristics of drug metabolism.

First, the parabolic fits imply the existence of a $\log P$ value ($\log P_0$) for which metabolic rate is predicted to be maximal. The authors interpreted this as a balance between increasing lipophilicity enhancing the ability of compounds to diffuse through the lipoidal membranes (*in vitro* or *in vivo*) to reach the active site(s) of the metabolizing enzyme(s) and the tendency, when lipophilicity is particularly high, to strongly adhere to lipids or lipophilic proteins, so slowing this necessary diffusive step. They observed that, across the range of series and systems they investigated, the mean $\log P_0$ was ~ 2.0 . Second, particular determinants of metabolic rate were observed for certain compound series. Thus, predictability of the *in vivo* rate of glucuronidation of primary aliphatic aldehydes was improved by incorporating E_s with a negative coefficient, indicating that as the site of glucuronidation becomes more hindered, the rate of glucuronidation increases, probably because the competing oxidative metabolism is more sterically demanding and becomes more strongly inhibited. This was not observed for secondary aliphatic alcohols, in which oxidation is already hindered.

Recent developments in *in vitro* assays for drug metabolism in drug discovery have tended toward the deployment of high throughput, standardized, assays within pharmaceutical and biotech sectors using isolated cells or subcellular fractions such as microsomes or S9 [29]. Routine use of these assays both provides the capability to generate large data sets of standardized data for model building and defines the framework within which predictions from models are judged. Chang *et al.* [66] generated models for intrinsic clearance (CL_{int}) in a rat hepatic microsomal incubation using an isocitrate dehydrogenase nicotinamide adenine dinucleotide phosphate (NADPH)-generating system. The model was developed using $\sim 28,000$ drug leads across a broad chemical space with a calculated $\log P$ normally distributed between -3.7 and 10 , molecular weights normally distributed between 140 and 839 , and intrinsic clearance strongly right-skewed between 1.57 and $989 \mu\text{L}/\text{min}/\text{mg}$ protein. The model was a two-way classifier to distinguish between those compounds with $CL_{\text{int}} \leq 87 \mu\text{L}/\text{min}/\text{mg}$ and those with $CL_{\text{int}} > 87 \mu\text{L}/\text{min}/\text{mg}$.

The model was a random forest and had an overall predictive accuracy of 83% on an internal test set and 77% on an external test set that was in a distinct area of property space from the training set compounds. Descriptors important in the model were a double-bond E-state descriptor, $\log P$, and fractional hydrophobic and fractional hydrophilic van der Waal's surface areas (which are completely correlated). The result is a potentially useful model, but the study illustrates the challenge in modeling xenobiotic metabolism to obtain useful results, even when using very large training sets.

The difficulty in predicting CL_{int} is unsurprising. Not only are xenobiotic-metabolizing enzymes promiscuous with respect to substrate structure [68,69], but CL_{int} is itself a composite property. For an enzyme displaying Michaelis–Menten kinetics, it is defined as the ratio of the maximal rate, V_{max} , and the Michaelis constant, K_m :

$$CL_{\text{int}} = \frac{V_{\text{max}}}{K_m} \quad (8.1)$$

Many compounds can be metabolized by a number of P450 isoforms present in the microsomal fraction so that the total rate of metabolism, v , is the sum of metabolic rates of the individual isoforms. If each of n isoforms displays Michaelis–Menten

kinetics toward a compound,

$$v = \frac{V_{\max,1} \cdot S}{K_{m,1} + S} + \frac{V_{\max,2} \cdot S}{K_{m,2} + S} + \cdots + \frac{V_{\max,n} \cdot S}{K_{m,n} + S} = \sum_i^n \frac{V_{\max,i} \cdot S}{K_{m,i} + S}$$

where S is the drug concentration at the active site of the enzyme.

In this case, the total intrinsic clearance is given by

$$CL_{\text{int}} = \sum_i^n \frac{V_{\max,i}}{K_{m,i}}$$

assuming that $S < K_{m,i}$ for all isoforms. Thus, for a compound that is metabolized by n isoforms, CL_{int} is a combination of $n V_{\max}$ and $n K_{m,i}$. Even for a compound whose rate of metabolism is quantitatively dominated by a single isoform, CL_{int} is a conflation of two composite parameters. Using the Briggs–Haldane definition of $V_{\max}$ and K_m for a single enzyme/isoform,

$$V_{\max} = E_0 \cdot k_2$$

and

$$K_m = \frac{k_{-1} + k_2}{k_1}$$

where E_0 is the total concentration of the isoform, k_2 the rate constant for the irreversible catalytic step converting the enzyme–substrate complex to generate the product, k_1 the association rate constant of the substrate and enzyme, and k_{-1} the corresponding dissociation rate constant of the enzyme–substrate complex. Thus, the two composite parameters of the Michaelis–Menten equation correspond to four different fundamental properties. E_0 is, in principle, measurable and, for the specific case where the rate of catalytic conversion is much less than the rate of dissociation of the enzyme–substrate complex ($k_2 \ll k_{-1}$), then

$$K_m \approx \frac{k_{-1}}{k_1}$$

which is the dissociation constant for the enzyme–substrate complex. Thus, in the simplest case, prediction of CL_{int} requires the implicit prediction of an underlying association step, which could be expected to be dominated by bulk properties relating to hydrophobicity/hydrophilicity, polarity, and hydrogen bonding, and of a transformative step, which could perhaps be expected to depend more on electronic and steric properties. The significant descriptors identified by the Chang model reflect the importance of hydrophobicity/hydrophilicity, hydrogen bonding, and electronic but not steric factors.

In contrast to the complexity inherent in attempting to predict CL_{int} in microsomes, predicting the properties of individual enzymes/isoforms offers a more tractable proposition. The difficulties should not be underestimated, because of the inherent promiscuity of drug-metabolizing enzymes, but the individual enzyme provides a far simpler system to understand than the complex microsomal fraction. In addition, the full

range of tools bringing in structural data about the isoforms concerned (Section 8.3) is available for studying these simpler systems, whereas the prediction of CL_{int} in multi-isoform systems, such as microsomes, is essentially limited to statistical methods, such as QSAR.

Ultimately, prediction of drug metabolism via the properties of individual isoforms should prove more valuable than prediction of, say, microsomal CL_{int} . This latter property can be measured in relatively high throughput screens, requiring a relatively small amount of compound [29]. Data on the effects of individual drug-metabolizing enzymes on a potential drug (such as the relative rates of metabolism, inhibibility by other drugs, and nonlinearity of metabolism), while being increasingly required by regulatory agencies and/or to predict likely population pharmacokinetics of clinical candidates compounds, are more expensive, time consuming, and/or require more compound to obtain. This combination of potentially providing greater cost savings, at the same time as offering problems that are more soluble indicates that prediction of the properties of individual drug-metabolizing enzymes is the route that offers greatest potential in drug discovery. That said, the advantage of developing models for microsomal CL_{int} is the very availability of data for model generation. The work of Chang *et al.* implies that a large “global” model for CL_{int} using data generated across many areas of chemistry has potential benefit in screening new chemistry and could thus be used to virtually screen libraries or hits for lead identification.

8.4.2 Drug Interaction with Specific Enzyme Isoforms

Changing the focus of study from composite systems (such as isolated cells, microsomes, or S9 subcellular fractions) to simpler systems, such as individual enzyme isoforms, increases both the toolset available for model development and the number of properties that can potentially be predicted. The additional tools include (Section 8.3) docking and molecular dynamics methods (where the crystal structures are available), field alignment methods, such as CoMFA and COMSIA, and pharmacophore methods. The additional properties that can be determined, and hence potentially predicted, with *in silico* models include various measures of the propensity of a particular enzyme isoform to metabolize a given compound or, alternatively, the propensity of a given compound to inhibit the metabolism of other compounds by a particular isoform. These are two different problems, though with common underlying bases that relate to the complementarity—in ways that need to be defined and determined—between a compound’s structure and the structure of active/allosteric sites on the enzyme form in question. Each of these problems must be tackled during drug discovery, and we address each in turn in the following sections.

8.4.2.1 Isoform-Specific Metabolism. The identities of the enzyme isoforms responsible for metabolizing a given drug, and the distribution of metabolism between them, determine the pharmacokinetics of a drug in a heterogeneous population, the potential for nonlinear pharmacokinetics as a consequence of enzyme saturation, and the potential for enzyme inhibition and induction to affect the drug’s pharmacokinetics, toxicity, and therapeutic efficacy. Experimental methods are available for identifying the enzymes, such as measuring metabolism in expressed enzyme systems or inhibiting metabolism in microsomes by isoform-specific inhibitors. Since metabolism plays

such an important role in determining the efficacy and toxicity of a compound, it is necessary to understand the metabolic fate of potential drug entities early on in the drug discovery process. A large number of compounds presented at this stage would render a full metabolic screen of them all unfeasible and therefore there is a clear need to develop reliable predictive models of metabolism instead.

First, we focus our attention to simply predicting whether a compound is a substrate for metabolism. This problem has been tackled using a wide variety of molecular descriptors and machine learning methods and we outline a few studies [70–73] in Table 8.1. The predictive accuracies for classifying whether a compound is a substrate of an enzyme isoform span the range 65–97%, but estimated accuracies depend on the chemical domain spanned by the training and validation sets, so it not a straightforward process to rank and compare models from different studies. However, given a compound is predicted to be a substrate, the conditional probability it is actually a

The predictive accuracy of each of the methods used is given.

substrate can be shown to be

$$P(\text{sub}|\text{pred}) = \frac{1}{1 + \frac{1-\text{Sp}}{\text{Se}} \times \frac{1-f}{f}}$$

The specificity (Sp) is the probability a nonsubstrate is correctly identified as being a nonsubstrate by the model. Likewise, the sensitivity (Se) is the probability a substrate is correctly identified to be a substrate by the model. Finally, f is the fraction of actual substrates in our total set of compounds. Taking the worst case scenario that the model accuracy is only 65%, and assuming this represents both the specificity and sensitivity,

$$P(\text{sub}|\text{pred}) = \frac{1}{1 + 0.538 \times \frac{1-f}{f}}$$

Therefore, if overall only 10% of the compounds are actually enzyme substrates ($f = 0.1$), then the model will predict a subset of these compounds to be substrates, 17% of which will actually be substrates. Thus, the model will have increased the proportion of substrates by almost a factor of 2, from 10% of the total set to 17% of the predicted subset. Using the model accuracy in this way can help judge whether applying a model for screening purposes would result in worthwhile savings in time and expense.

In silico docking is a computationally expensive method of predicting drug metabolism and therefore cannot be routinely used to screen large numbers of compounds. It is particularly valuable, however, for providing an atom-level understanding of the drug–enzyme binding complex and has been used to study drug binding to CYP2D6 [74]. This study revealed that metoclopramide can adopt two positions in the enzyme active site, but only one of these binding conformations had been observed experimentally. Analysis of the second binding conformation implied the production of a second metabolite that had not previously been identified, but which was later verified by experiment.

Molecular dynamics simulations, like *in silico* docking methods, are computationally demanding but can provide insight into the mode of binding for a small number of drugs. Seifert *et al.* [75] analyzed the dynamics of warfarin in the active site of CYP2C9. The crystal structure of this warfarin-bound complex cannot by itself predict the subsequent metabolites, as the warfarin sits too far away from the catalytic heme group. Molecular dynamics simulations, on the other hand, revealed two ways of binding to this catalytic center, resulting in the formation of the two experimentally observed metabolites. In a more recent study [76], the role of water within the active site of CYP2D6 was investigated using molecular dynamics simulations. Hydration sites were identified and these water molecules, when included in an *in silico* docking protocol, improved the reliability in predicting the sites of metabolism for methylenedioxy-*N*-methylanphetamine.

Both docking and molecular dynamics methods predict the site of metabolism on a compound by identifying the energetically favorable binding conformations in the active site of an enzyme. The compound atom that predominantly interacts with the catalytic group of the active site is identified as being the site of metabolism. In the absence of an enzyme structure, an alternative way of estimating possible sites of metabolism is to consider the electronic environment surrounding the hydrogen

atoms of the compound [77,78]. If it is assumed that removal of the hydrogen is a rate-limiting step, then hydrogen atoms requiring least energy to dissociate from the molecule are most likely to be at the sites of metabolism. Calculating dissociation energies requires expensive quantum mechanical calculations, but semiempirical methods have been developed, which reduce the computation time with minimal compromise on accuracy [79]. Although these methods are far too costly to be used in early stage drug discovery, it has been proposed that there is potential value in employing these methods to assess metabolic transformations of lead compounds in the preclinical phase [78].

8.4.2.2 Inhibition of Metabolism. While some drugs are metabolized by CYP450 or UGT enzymes, other drugs will inhibit this metabolism, potentially resulting in drug–drug interactions that may compromise the success of clinical trials. Prediction of enzyme inhibition in early drug discovery is becoming increasingly important and we summarize several studies of this kind in Table 8.2 [43,73,80–82].

The studies summarized in Table 8.2 show that compounds can be predicted to be strong or weak enzyme inhibitors with an accuracy ranging from 66% to 96%, with the support vector machine method developed by Yap and Chen [73] achieving accuracies at the higher end of this range.

Kriegel *et al.* [80] applied partial least squares methods to a combination of 2D, 3D, and quantum mechanical descriptors resulting in an overall accuracy of 66%. In addition, a model based purely on quantum descriptors (accuracy of 54%) did not outperform a model composed purely of 2D descriptors (accuracy = 58.3%). This is surprising as unlike 2D descriptors, quantum mechanical descriptors are derived from the 3D chemical structure, and a molecule's electronic structure offers great insight into its binding potential. However, on this evidence, it seems the considerable computational overhead required to calculate quantum mechanical descriptors does not translate to increased predictive ability.

Hudelson *et al.* [81] built four models to predict compounds that inhibit CYP2C9, the predictive ability ranging from 74% to 90%. To increase reliability, it was proposed that a prediction should only stand when all four models agreed whether a compound was an enzyme inhibitor. Surprisingly, there was agreement across all four models for only two thirds of the compounds tested, and so in this case, one-third of compounds could not be classified. This stringent rule was then relaxed so that a result would stand if at least three of the models agreed, increasing coverage to the majority of compounds and resulted in a predictive accuracy of 91%.

Vasanthanathan *et al.* [82] tested a variety of models on a large test set of 7000 compounds, resulting in predictive accuracies in the range 67–76%, and since the test set is so large, these values can be taken to be a reliable measure of the predictive accuracy of enzyme inhibition by machine learning methods. The nonlinear support vector machine and random forest methods gave slightly superior accuracies, 75% and 76%, respectively. At the other end of the scale, a decision tree based on Lipinski's rule-of-five descriptors managed to classify 67% of test compounds correctly. However, this decision tree is easy to interpret and provides structural insight into CYP1A2 inhibitors—hydrophobicity and hydrogen bond donors/acceptors being important features for classifying CYP1A2 inhibitors. This structural interpretation is not as transparent from the machine learning methods. On balance, one must decide

whether the additional accuracy obtained from machine learning methods offsets the ease of use and straightforward interpretation of the Lipinski's rule of five.

Finally, as mentioned in Section 8.4.2.1, the computational expense of the docking method restricts its application to a small number of compounds. That said, Marechal *et al.* [43] were able to discriminate well between strong ($k_i < 10 \mu\text{M}$) and weak ($k_i < 100 \mu\text{M}$) inhibitors using this technique, but its main selling point is in the detailed structural information it reveals regarding the mode of binding in the active site of the enzyme.

8.4.3 Transporters

8.4.3.1 Identifying Substrates for Transporters. To fully understand drug metabolism and drug–drug interactions, one must consider active transport into and out of cells as it may be significant compared with passive diffusion for certain drugs, and there has been corresponding interest in developing *in silico* prediction models to predict transporter activity [83].

In Table 8.3, we summarize results from selected studies that have developed QSAR models to predict the affinities for a range of transport proteins: P-glycoprotein, organic cation transporters, and nucleotide transporters [84–91]. Osterberg and Norinder [84] conclude that variables associated with hydrogen bonding and high polarizability correlate with high P-glycoprotein ATPase activity. Other studies also highlight the importance of hydrophobic features [90–92], which may represent aliphatic or aromatic hydrophobes [92].

8.4.4 Induction of Metabolizing Enzymes or Transport Proteins

The PXR is a nuclear receptor that regulates the expression of metabolizing enzymes and P-glycoprotein efflux transporters. A drug activating PXR can therefore influence the metabolism and transport of itself, or a second drug dosed simultaneously, and may lead to drug–drug interactions. A pharmacophore for PXR ligands has been identified by Ekins and Erickson [93] and consists of hydrogen bond acceptor and hydrophobic features, similar to the pharmacophore for CYP3A4 substrates and inhibitors, but in different positions. The pharmacophore alone was able to differentiate very potent activators from weak activators. More involved methods are required to build more reliable predictive models for PXR activation, some of which are summarized in Table 8.4 [94–96].

A comparison of the predictive accuracies obtained by Ung *et al.* [94] and Khandelwal *et al.* [95] reveals that the support vector machine method is superior to other methods investigated. The predictive accuracies obtained by Ung *et al.* were roughly 10% greater than those achieved by Khandelwal *et al.*, even when they both used the support vector machine technique. The most likely explanation for this discrepancy is perhaps in the calculation of the accuracy statistics, rather than the way in which the methods were applied in the two studies. Khandelwal *et al.* used a 145-compound test set to measure the predictive accuracy, whereas Ung *et al.* adopted a 10-fold cross-validation study in which the test sets each contained only 20 compounds. The larger test set of Khandelwal *et al.* could conceivably cover a greater area of chemical space

and would therefore be a greater test of the model's ability to predict human PXR activators.

In contrast to the machine learning methods, *in silico* docking as employed by Ekins *et al.* [96] resulted in a much worse predictive accuracy, barely greater than a 50–50 guess. However, the authors also investigated the performance of 3D-, 4D- and 5D-QSAR. Surprisingly, 3D-QSAR methods, such as CoMFA and CoMSIA, also performed poorly, a reason being that the PXR active site is flexible, allowing small molecules to bind in several orientations. In CoMFA and CoMSIA, the compounds must be aligned and so these two methods would not capture the multiple orientations, which contribute to the overall observed enzyme activation. 4D-QSAR, on the other hand, does consider multiple conformations, orientations, and stereoisomers of each compound and improved the predictions for the training set compounds, although the prediction of the test set compounds was still poor. 5D-QSAR is an extension of 4D-QSAR, also considering the induced fit of the compound in the active site of the protein, and was the only QSAR method capable of making test set predictions of steroidal PXR activation with a reasonable level of success.

8.4.5 Physiologically Based Models

The modeling approaches discussed hitherto only provide information about the existence or extent of the interaction between a compound and a protein. These data may be useful in early stage drug development, providing an indication of the likelihood of such an interaction, but do not provide any indication of the clinical significance of this interaction: crudely, if significant interactions occur only when the test compound concentration is greater than some lower bound, we also need to know the time for which the compound concentration is greater than this lower bound after the compound is dosed. To obtain information about the clinical significance of a compound–protein interaction, it is necessary to integrate interaction data with pharmacokinetic data. Indeed, interactions between a compound and metabolizing enzymes or transport proteins determine the compound's pharmacokinetics.

8.4.5.1 Single-Compound Pharmacokinetics. The use of physiologically based pharmacokinetic (PBPK) models to predict or model pharmacokinetics has been widely discussed [97–100] and the prediction or modeling of single-compound pharmacokinetics is a prerequisite of the prediction or modeling of interactions between compounds. A number of commercial products exist or it is possible to implement basic PBPK models in-house.

The gross structure of a whole-body PBPK model is shown in Fig. 8.1. Dosed compound flows with blood from the arteries through the organs into which it can distribute or from which it may be cleared from the body. After passing through the organs, compound arrives in the venous blood, from which it enters the pulmonary circulation and then flows back into the arteries. While this gross structure is generally agreed, the variations that are observed in the details of PBPK models mean that there is as yet no well-defined and agreed generic structure for a PBPK model that can be relied on in all situations. Different groups model different organs, and sometimes organs, particularly the liver, are supposed to be segmented [101]. Other models include the dynamics of plasma protein binding and transport effects in the

Figure 8.1 The structure of a generic PBPK model. Boxes (“compartments”) represent blood pools (arterial and venous), organs, and tissues. Arrows represent blood flows between compartments. Different models differ primarily in the number of organs and tissues that are explicitly represented.

liver [102,103]. Sometimes organs are lumped into “central” and “peripheral” compartments [104,105]; this makes a model less physiological, but may make it easier to parameterize from *in vivo* data. Organs are commonly modeled as being well-stirred, with rapid equilibration of free compound between plasma and tissue; but taking typical values for compound permeability, it seems that this rapid equilibration may be an unrealistic assumption [105–107]. In any case, to model transporter effects, it is necessary to include permeability barriers in the organ model; organs are sometimes subdivided into blood, interstitial, and intracellular compartments [108]. The inclusion of transporter effects is a relatively recent development [109–115].

The modeling of absorption from and transport along the GI tract is an art in itself. Physiological models of the GI tract consist of a sequence of segments through which flow dissolved and undissolved compound (Fig. 8.2), with some modeling of dissolution, and with absorption of the dissolved compound [12,107,116,117]. Metabolism in the walls of the GI tract is also sometimes included [118,119].

The extent of distribution in PBPK models is predicted using a competition between partitioning into tissue lipids and binding to plasma proteins. A few variants on the idea are reported in the literature [120–122]; as yet there is no definitive method. The octanol–water partition coefficient is commonly used as a measure of lipophilicity; some groups use, instead, affinity to phospholipid membranes [123,124], and there does not seem to be agreement on the best measure of lipophilicity to use in general. It should be noted that these models rely on the partition coefficient directly rather than on its logarithm: an error of half a log unit in the logarithm translates to a threefold error in the partition coefficient and—for lipophilic compounds—a threefold error in the volume of distribution even before difficulties in the measurement of plasma protein binding are taken into account.

It is also necessary to parameterize the rate of metabolism in a PBPK model. If *in vivo* data are available, one can just optimize the model to fit the measured data, but if they are unavailable, one must predict the rate of metabolism using *in vitro* or *in silico* data. The prediction of metabolic clearance from *in vitro* data has recently

Figure 8.2 The generic structure of gastrointestinal tract absorption modeling in PBPK. The GI tract is treated as a series of segments (compartments) in sequence. Dissolved and undissolved compound plus water (more precisely the gastric or intestinal fluid) flows from a compartment to the next in the series. Dissolved compound is available for absorption across the GI tract epithelium into the body, which can be represented by a PBPK model (as in Fig. 8.1). Different models differ in the number of segments that are used to represent each part of the tract.

been reviewed [125]. Large uncertainties and variabilities in the *in vitro* data mean that, generally, predictions of *in vivo* clearance based on *in vitro* data alone can be statistical at best.

Some success is reported in using generic PBPK models for statistical predictions of pharmacokinetic parameters such as clearance [108,126] and, until the details of mechanistic extrapolation from *in vitro* to *in vivo* are resolved, this is perhaps the most that can be expected from predictive PBPK modeling in early drug discovery. Later in drug discovery and in drug development more effort can be expended on developing a customized and optimized model for a particular compound, when *in vivo* data are available for the calibration of such models. These optimized models can be used for explanatory purposes [127] and to design detailed *in vivo* trials that assess specific aspects of pharmacokinetics [128]. The detailed analysis of such models allows the determination of the controlling parameters and can give good mechanistic understanding of *in vivo* pharmacokinetics [127,129].

8.4.5.2 Interactions Between Compounds. The interaction most commonly modeled mechanistically is the inhibition of CYP-mediated metabolism. PBPK models are separately developed for each interacting compound using *in vitro* or *in vivo* data. These models are used to predict compound concentration at the critical sites for drug–drug interaction such as the liver or intestinal mucosa. *In vitro* interaction data

can then be inserted to link the two models. A relatively detailed model of metabolism is necessary: in general, compounds may be metabolized by multiple enzymes, so to model correctly the effect of the inhibition of a given enzyme, one must account for the relative contributions of all enzymes that significantly metabolize the compounds in question. For compounds that can be modeled with single-enzyme metabolism, this step is unnecessary, but this will not in general be the case. Interactions between more than two compounds can be handled in a similar way. Irreversible inhibition, in which a metabolizing enzyme is permanently inactivated, demands a different type of model to reversible inhibition. To predict irreversible inhibition, some idea is needed about protein turnover [130]; the actual protein concentration must be evolved as part of the simulation.

Successes for this approach have been reported in the literature (Table 8.5) [101,104,105,119,123,130–137]. Some use mechanistic PBPK modeling to predict single-compound pharmacokinetics; others use a more empirical approach in which physiological or semiphysiological models of single-compound pharmacokinetics are fit to *in vivo* data. The overwhelming majority study CYP3A, presumably because CYP3A-family enzymes are the most common drug metabolizers.

In principle, this general approach could also be used for interactions controlled by the inhibition of active transport; all that is needed is a mechanistic model of transporter activity *in vivo* [109–112,114] coupled to some *in vitro* transporter inhibition data.

But while these are all promising successes, it must of course be noted that, as discussed above, the quantitative prediction of even single-compound pharmacokinetics is challenging. It would be surprising if prediction of drug–drug interactions was simpler than the prediction of plasma clearance: a mechanistic model of metabolic drug–drug interaction requires, to some extent, an understanding of metabolic clearance. Given the challenges in the quantitative prediction of metabolic clearance from *in vitro* data [125], it is easy to see how difficult it is to accurately predict *in vivo* inhibition of metabolism.

Heuristic models of CYP induction relate the extent of *in vitro* induction to the rate of *in vivo* metabolism [138]. This essentially applies sensitivity analysis to the single-compound pharmacokinetics: develop a working model for the victim compound in base conditions and just rerun the model using various hypothetical rates of metabolism following induction.

Mechanistic models of enzyme induction require some concept of protein turnover and gene expression [139] and require the enzyme concentrations to be evolved as part of the simulation. There are two mechanisms for CYP induction that have been modeled. Both result from a change to the balance between protein synthesis and degradation: the more common mechanism is an increase in protein synthesis following nuclear receptor binding, the less common is a decrease in protein degradation due to stabilization caused by xenobiotic binding to the protein. Some of the mechanistic induction models found in the literature are given in Table 8.6 for induction by dioxin [140–144], isoniazid [145], phenobarbital [146], artemisinin [147], and cyclophosphamide [148]; these are all customized models for a particular interaction and are not *a priori* predictive.

8.5 INCORPORATING IN SILICO METHODS IN DRUG DISCOVERY

In previous sections, we have described a number of *in silico* methods and discussed some specific applications to predict drug metabolism and drug–drug interactions. These methods perform an important function by helping increase our understanding

of the properties of compounds that determine their fates and interactions *in vivo*. To have maximum impact, however, in a drug discovery program, the methods must support and inform the selection of (virtual) compounds to be synthesized or (real) compounds to be selected for screening assays. In this section, we consider ways whereby the methods can be incorporated into the drug discovery process, with a view to inform and help direct medicinal chemistry efforts toward designing compounds with required characteristics. In this respect, the methods so far described do not stand alone. The capability to beneficially employ them in drug discovery depends on

- the availability of necessary supporting software;
- appropriately skilled and experienced staff;
- effective communication between modelers, drug metabolism/pharmacokinetics (DMPK) scientists, and medicinal chemists.

This can be illustrated with a simple example in which systemic clearance is to be predicted in order, for instance, to estimate plasma half-life. In this case, the effect on predicted *in vivo* plasma clearance of uncertainty in a prediction of hepatic clearance diminishes in relative importance as the predicted hepatic clearance increases toward hepatic blood flow. This is intuitively apparent from the effect of blood flow on limiting clearance, but sensitivity and error analyses of PBPK models can quantify the effect, can process large numbers of compounds in a short time, and can do so for those less obvious relationships that can exist between model inputs and outputs. Use of sensitivity and error analysis can thus indicate the acceptable bounds in uncertainty and bias on any given prediction or set of predictions.

As a simple, illustrative, example, we can first consider the case of predicting lipophilicity, in the form of the octanol/water partition coefficient, P . The partition process can be viewed as the creation of cavities in the two solvents (octanol and water)—an endoergic process—and the insertion of a solute into the solvents, which gives rise to various solute/solvent interactions (hydrogen bonding, electrostatic, van der Waal's, etc.), which may be endo- or exoergic. The balance of these processes will determine the overall energy change, and hence equilibrium position, of the partitioning (Fig. 8.3). Many *in silico* methods exist for this property (reviewed in Refs 149 and 150), but the method of Abraham and coworkers [151] has made the above relationships explicit:

$$\log P_{\text{oct}} = a + b \cdot E - c \cdot Z + d \cdot A - e \cdot B + f \cdot V$$

where $\log P_{\text{oct}}$ is the logarithm (base 10) of P . E , S , A , B , and V are properties of the particular solute:

- E is the excess molar refraction.
- Z is the polarizability/dipolarity.
- A is the hydrogen bond acidity (donor capability).
- B is the hydrogen bond basicity (acceptor capability).
- V is the McGowan's characteristic volume.

Figure 8.3 Relationships between Abraham descriptors, compound characteristics, and lipophilicity. V , A , B , Z , and E are the Abraham descriptors.

$a-f$ are constants with specific values for any partitioning system. For octanol/water, the partitioning is dominated by fV (i.e., molecular size, which favors octanol) and eB (hydrogen bond basicity, which favors water). E and V can be calculated for a compound directly from atom and bond contributions, whereas S , A , and B require manual summation from specified molecular fragments. While more accurate $\log P$ predictors currently exist [149,150], in terms of implementation in a drug discovery process, the Abraham method has the following points in its favor:

- The model involves a limited number of (six) unknown parameters, reducing the risk of being overtrained on reasonably sized training sets.
- The descriptors are readily interpretable in terms of fundamental properties of compounds.
- The small number, and the nature, of the descriptors facilitates their understanding by nonspecialists.
- The model is linear with respect to its descriptors, so that the way in which changes in any descriptor's value affects the predicted $\log P$ is clear.

The problems of interpreting and utilizing metabolism and drug interaction are harder than the analogous problem for $\log P$. Involving, as they do, interaction between a small molecule (or, in the case of drug interactions, two small molecules) and an enzyme or transporter protein active site, simple explanations are less frequent and correlations are weaker than for $\log P$. Additional properties, relating to molecular shape are more important and such properties are, of necessity, less amenable to simple interpretation. Lewis [152] has collated information from a number of sources to specify characteristics of individual human P450 isoforms, in a qualitative/semiquantitative manner in terms of planarity, acid/base characteristics, volume, and lipophilicity. Lewis [153] has also defined QSARs for substrates (and inhibitors) of the human P450 CYP2 family (2A6, 2B6, 2C8, 2C19, 2D6, and 2E1) in terms of a small number of readily definable descriptors, including lipophilicity, molecular weight, and hydrogen bonding capability. These QSARs have, however, been generated using small data sets so, while they can provide some useful insight into potentially important features that define

substrate specificity, the ability of the QSARs to extrapolate to other compounds is doubtful. Methods for predicting CYP450 substrate specificity have been reviewed by Ekins *et al.* [154] and de Groot [155].

Turning in more detail to the identification of CYP3A4 substrates, the key CYP450 isoform for drug metabolism in humans, a number of approaches, including pharmacophore [156], QSAR [72,73], and docking [157], have been attempted.

Balakin *et al.* [72] developed a model for the Michaelis constant, K_m , of CYP450 substrates. As we have discussed in Section 8.4.1, the Michaelis constant does not, by itself, predict the rate of metabolism of a compound. For this, the V_{max} is also required. The Michaelis constant does, however, provide information about binding to the active site, potential for nonlinearity in metabolism, and potential for drug–drug interactions mediated by inhibition of metabolism. For CYP3A4, Balakin *et al.* had experimental K_m values for 126 compounds, categorizing the values as low ($< 10 \mu M$), medium ($10\text{--}100 \mu M$), or high ($> 100 \mu M$). For differentiating between low and high (ignoring medium) K_m values, six descriptors were found to be important. Listed in order of decreasing importance, these are as follows:

1. Zagreb (a measure of topological complexity).
2. Number of H-bond acceptors.
3. Number of rotatable bonds (a measure of flexibility and also correlated to size).
4. A measure of partial negative surface area (PNSA-1).
5. Number of H-bond donors.
6. $\log P_{oct}$.

For all except the two hydrogen bonding descriptors, the differences were statistically significant by a two-tailed t test (Table 8.7). It can thus be seen that the most important determinant between low and high K_m is a complex descriptor (Zagreb), whose interpretation is not obvious—and therefore whose utilization in guiding medicinal chemistry is not trivial. Consequently, to use the results of this model to guide chemistry, medicinal chemists would require appropriate computational tools and/or databases, either to screen libraries for compounds or to design compounds having appropriate properties [158–160]. Three of the properties (numbers of hydrogen bond acceptors and donors and number of rotatable bonds) are more amenable to quick assessment, as is $\log P_{oct}$ (on the assumption that $\log P_{oct}$ predictive software is almost ubiquitous and/or chemists would rapidly gain experience in estimating the lipophilicity

TABLE 8.7 Important Descriptors for Differentiating Between Strong and Weak Binders to Human CYP3A4

Property	Mean Value for Strong Binders ^a	Mean Value for Weak Binders ^a
Zagreb index	~ 210	~ 120
Number of rotatable bonds	9	4
PNSA-1	~ 260	~ 175
$\log P_{oct}$	~ 4.8	~ 2.6

^aStrong and weak binders are distinguished by low ($< 10 \mu M$) and high ($> 100 \mu M$) K_m , respectively.

within a particular series). Furthermore, by inspection of Table 8.7, it can be seen that the model predicts marked differences in $\log P_{\text{oct}}$ and the number of rotatable bonds for strong and weak binders, so there are some, at least, clear, readily identifiable differences between strong and weak binders.

Yap and Chen [73] adopted a different approach, identifying compounds as CYP3A4 substrates or nonsubstrates (368 and 334, respectively) on the basis of reports—or lack of such—in the literature of a compound being metabolized by a particular P450. The groups of descriptors that were selected as important during the modeling process were mostly composite, and therefore difficult to interpret, namely

- 3D-MorSE—encode 3D features such as van der Waal's volume, electronegativities, and polarizabilities.
- Radial distribution function (RDF)—encode information about bond lengths, ring types, planar and nonplanar systems, and atom types.
- Randic molecular profiles—encode interactions between atoms in a molecule and information on molecular shape.

The simpler, noncomposite, descriptors ($\log P$, hydrogen bond acceptors and donors, etc.) provided less information about the substrate/nonsubstrate (and, analogously, the inhibitor/noninhibitor) classification of substrates with respect to CYP3A4. Thus, substrates had mean Moriguchi $\log P$ of 2.2 ± 1.9 compared with 1.6 ± 2.06 for nonsubstrates. This contrasts with the findings of Balakin [72], where low and high K_m compounds were differentiated by statistically significant mean $\log P$ of ~ 4.8 and ~ 2.6 , respectively (Table 8.7). The difference arises both from the nature of the problem being addressed and the amount of information being sought. Identifying whether a compound is a substrate for metabolism of CYP3A4 is more difficult than identifying whether it binds tightly to the protein's active site, in which bulk-phase hydrophobic interactions can exert a significant effect. Yap and Chen were, furthermore, seeking a classification for all possible compounds into substrate/nonsubstrate, whereas Balakin *et al.* had restricted themselves to the widely separated classes of low and high K_m compounds and were not attempting to address the intermediate category of medium K_m (between 10 and 100 μM).

The study of Ung *et al.* on the activation of PXR also provides interesting insight into the interpretation of molecular descriptors and their potential for informing medicinal chemistry [94]. They point out the tremendous range of compounds that are known to be activators, and the range of structural features they exhibit, including aromatic and saturated multiring structures, halogen- and oxygen-rich compounds, and compounds with chain-like structures, such as discodermolide and β -carotene. This is consistent with PXR's flexible, predominantly hydrophobic, binding site that permits binding of a wide range of substrate sizes in multiple conformations [161]. Despite the flexibility of the site, which might lead to the expectation that complex descriptors would be preferred in the model, certain molecular descriptors were selected that are related to identifiable structural features in compounds. Table 8.8 lists some of these descriptors and their values for activators and nonactivators. These descriptors relate to size, polar surface area, flexibility, and the number/electronic and topological state of certain types of heteroatoms (nitrogen and halogens). The number of rotatable bonds and Kier molecular flexibility index indicate that, on average, activators are slightly smaller and less flexible than nonactivators. Polar surface area is slightly lower for activators

TABLE 8.8 Selected Descriptors for Differentiating Between Activators and Nonactivators of Human Pregnane X Receptor

Property	Activators ^a	Nonactivators ^a
Number of rotatable bonds	4.45	5.99
Kier molecular flexibility index	5.84	6.24
Polar surface area	61.9	69.5
Number of halogens	1.16	0.8
Number of chlorines	1.02	0.27
Number of nitrogen atoms	0.8	1.79
Atom-type E-state sum for chlorine	6.33	1.63
Atom-type E-state sum for >NH	0	0.45
Atom-type E-state sum for =N-	0.31	1.15
Atom-type E-state sum for >N-	0.15	0.94

^aFigures are the mean values for compounds predicted by the model to be activators or nonactivators.

(although it might not be so when normalized for molecular size). Activators tend to have more halogen and less nitrogen atoms than nonactivators. However, for simple descriptors (numbers of rotatable bonds, halogens, chlorines, and nitrogens), the differences are small, particularly when taking into account that the values are limited to integers; these descriptors may not be particularly informative. Thus, the presence of four or five rotatable bonds is more likely to indicate an activator than nonactivator, while six is more likely to indicate an activator. One chlorine is more likely to indicate an activator than a nonactivator, but a significant proportion of nonactivators must have at least one chlorine. For halogens, in general, there is very little difference between the mean values for activators and nonactivators, both of which are close to 1. Two nitrogen atoms in a molecule are more likely to indicate a nonactivator, while one is more likely to indicate an activator.

While being less amenable to immediate interpretation, the E-state indices [162], which encode information about the electronic and topological environment of particular atoms, offer the potential for greater discrimination on a continuous scale. Thus, the E-state values for chlorine and for different bonding configurations of nitrogen (see the last five rows of Table 8.8) provide such information for discriminating between activators and nonactivators of human PXR, in which the nonintegral mean values and values between them can have a true meaning. Thus, it can be immediately inferred from the mean number of chlorine atoms in predicted nonactivators (0.27) that a significant proportion of them must have at least one chlorine atom. In contrast, the nonintegral values of the E-state sums of chlorines in predicted activators and nonactivators (6.33 and 1.63, respectively) provide information about the number of chlorines, and the modulating electronic field effects of the other atoms in the molecule, weighted by their topological distance (i.e., the number of bonds) from the chlorine(s). Similarly, the mean numbers of nitrogen atoms in predicted activators (0.8) and nonactivators (1.8) indicate some uncertainty around the status of compounds having one nitrogen atom. Again, the relative values of the E-state indices for the different configurations of nitrogen are well separated, helping distinguish between the two classes of compounds. The drawback in using such descriptors has already been addressed in reference to the model of Balakin *et al.* for CYP3A4 binding.

A further means of exploiting predictions of drug metabolism and drug interactions is to use them as inputs to appropriate PBPK models, linking the prediction of a drug's properties to its expected behavior *in vivo*. Sensitivity/error analysis of a PBPK model (i.e., the quantification of the dependence of its outputs on the value of any of its inputs) will provide information about how uncertainty and/or bias in the predictions of a drug's property will affect its expected behavior *in vivo*. This type of analysis makes use of the ease of rerunning simulation models with appropriate variation of the input and can be used in one of two related ways:

1. By scanning an input value through a (potentially hypothetical) range and recording the predictions of the PBPK model for each input value, the sensitivity of the predictions to the value of the input can be ascertained. This is known as *sensitivity analysis*.
2. By sampling the predicted distribution of the input (which can be generated from the error statistics of the model that generates the input), the corresponding distributions in the PBPK model's predictions can be determined. This is an aspect of *error analysis*.

Because PBPK models require quantitative inputs on the whole, the most effective use of this approach requires that the models for the input properties generate quantitative values or classifications with classes with well-defined upper and lower limits. As we have discussed, many models for predicting drug metabolism and drug–drug interactions are binary classification models (i.e., for substrate/non–substrate and inhibitor/noninhibitor), so there is still significant progress to be made in model development in this area to realize the prediction of *in vivo* behavior from *in silico* metabolism and drug interaction models.

We complete this section by emphasizing that DMPK represents just one part of a drug's property set and that the significance of its DMPK properties—whether determined by experiment or by *in silico* modeling—has to be viewed in the context of its other properties, particularly its on-target and off-target pharmacology. Of the properties we have discussed in this chapter, it is particularly important to view those that can cause drug–drug interaction (i.e., inhibition of metabolism and induction of metabolism/transport) in this context. The propensity of any potential new drug to actually cause such interactions *in vivo* is dependent on the concentrations it is required to achieve *in vivo*. These are, in turn, governed primarily by its activity against its target(s). Low activities against targets will require high concentrations *in vivo*, increasing the likelihood of interactions with other drugs. In a similar manner, the most effective use of PBPK models that can predict plasma concentrations is dependent on knowledge of the expected therapeutic window of the compound, which is in turn determined by its primary pharmacology and its dose-limiting toxicity. The most efficient screening strategies will be those that bring together useful data in pharmacology, toxicity, and DMPK, each having similar costs of information relevant to the particular stage of the discovery process. This could entail a combination of *in vitro* and *in silico* data, the balance between the two depending on the cost of information. High throughput *in vitro* screens for drug metabolism properties [66,163] are able to generate the large amounts of data required for producing reliable models and also reduce the cost of generating primary assay data, potentially reducing the need for predictive models. Set against this, the use of systems for automated QSAR model development [164] can

drastically reduce the time and cost of model development and their regeneration from evolving data sets. If target activity can be predicted *in silico*, so permitting hits to be identified virtually, then the ability to predict metabolic and *in vivo* drug–drug interaction properties can result in a significant recovered opportunity cost by permitting deferral of the synthesis of potentially unsuitable compounds [66].

8.6 CONCLUSIONS

In silico methods are making significant contributions to our growing knowledge of the factors that determine how drugs and other xenobiotics are processed *in vivo*. Numerous methods have been developed and employed over the past 30 years. In this chapter, we have endeavored to do justice to a number of these methods, to their contributions to the furthering of knowledge and their practical applications in the drug discovery process. We have described two major areas of application. Each area is extremely complex in its own right; this must be borne in mind when assessing current capabilities and future progress.

The first is concerned with the prediction of interactions between drugs and individual proteins (drug-metabolizing enzymes, transporters, and nuclear receptors), including the simultaneous interactions of multiple drugs with an enzyme or transporter that can give rise to mutual or unilateral inhibition of metabolism or transport. The complexity in this area arises from the well-documented promiscuity of the proteins involved. A given enzyme/transporter/receptor can metabolize/transport (or be inhibited by)/be activated by multiple xenobiotics. A given xenobiotic can be metabolized by/transported by (or inhibit)/activate multiple proteins. The challenge of *in silico* modeling is to identify those interactions that will/will not occur, and the strength of those interactions, as measured by rates of metabolism or transport, binding constants, inhibition constants, and so on. For many of the applications we have described, a large part of the challenge entails the collation of a reliable data set of a large enough size for model development. For any given problem, it is not guaranteed that a suitable data set can be generated, because of the huge number of combinations of xenobiotic/protein interactions that must be considered. For example, development of a QSAR model to discriminate between the metabolism of compounds by (say) four isoforms of CYP450 requires reliable data for each compound and for each isoform. It frequently arises that the absence of reported metabolism of a compound by a particular isoform is taken to indicate that the compound is not metabolized by that isoform but this is not, of course, the same thing. Without definitive data, such assumptions can compromise the modeling process from the start. Extend this to the myriad other interactions of interest—with UGT enzymes, ABC transporters, nuclear receptors, and so on, and the whole model development and application structure can be fatally undermined. Improvements in reliable, high throughput, low volume assay methodologies will significantly increase the availability of reliable data for model development in the future.

In assessing the progress and utility of *in silico* model development in this area, the differences between practice in the drug discovery industry and the majority of reports in the scientific literature must be borne in mind. Many the papers we have discussed in Section 8.4 have shown modest predictive ability for a range of properties related

to drug metabolism and drug–drug interactions. We should not be surprised with these results, given the data available, the relatively small data sets, and the diversity of the compounds that can be processed by, or bind to, the proteins in question. These types of models are generally termed *global* models, in that they are generated using data for compounds scattered across a wide range of chemistry—almost invariably using data on marketed drugs. This is not necessarily because of the desire to generate global models, but because of the limitations of data availability in the public domain. The practicalities of drug discovery are different. Discovery projects focus on a small number of specific areas of chemistry, so chemical diversity (and the problems introduced by this) is much reduced. The need for a model to extrapolate or interpolate into an area of chemical space that is poorly represented in the training set is consequently reduced. This matter has been discussed by Weaver and Gleeson [49] in relation to the development of QSPR models for predicting plasma protein binding and inhibition of CYP3A4-mediated metabolism. It seems reasonable to regard the prediction statistics of global models as a lower bound on what should be achievable with models on more focused areas of chemistry.

The second application area we have considered is that of PBPK modeling, by means of which data (whether from *in vitro* or *in silico* sources) on drug metabolism and drug–drug interactions can be integrated to predict *in vivo* outcomes. The key modeling challenges for the prediction of drug–drug interactions are (i) to predict the concentrations of drugs at the active sites of the relevant enzymes/transporters and (ii) to be able to appropriately scale, if necessary, kinetic parameters (e.g., $V_{\max}$, K_m , and K_i) to the *in vivo* case. These two are dependent, as the ability to predict concentrations depends, in part, on the scaling of kinetic parameters of drug transport and metabolism. The complexity in this case arises from the multiple potential *in vivo* processes (absorption, distribution, metabolism and elimination, each potentially via multiple competing routes) to which a xenobiotic can be subject and which affect prediction of drug concentration at the active site(s). In most cases, in drug discovery and development, appropriate data required to model some—maybe most—of these processes will be lacking. Therefore, predictions must be interpreted in the light of what is, and what is not, known about the processes affecting the fate(s) of a particular compound *in vivo*. The evolution of predictive PBPK models is absolutely dependent on the development of appropriate assays for these processes and the knowledge to enable data to be successfully scaled to the *in vivo* case. This knowledge frequently lags significantly behind assay development and is frequently a significant impediment to new applications of PBPK modeling. Having said that, we have described a number of applications where the technique has already been used to provide valuable information and interpretation concerning *in vivo* drug metabolism and drug–drug interactions.

It can be seen that *in silico* techniques are able to provide valuable insight and predictivity regarding drug metabolism and interactions *in vitro* and *in vivo*. Significant work remains to be done on improving predictability for known routes of metabolism and transport, and the challenge is continually growing as further routes are discovered, and hence opportunities for drug–drug interactions to arise are identified. In fact, this very increase in the known complexities involved in drug metabolism and interactions requires that the contribution of *in silico* methods in this area increases to help keep drug discovery costs under control and to inform and guide the discovery selection process.

9.1 SUMMARY

Determination of the *in vitro* kinetics of metabolism of drugs is critical to the drug discovery and development process. This typically involves using some type of enzyme system (e.g., human liver microsomes, expressed enzymes, and hepatocytes) to measure metabolite formation rates and enzyme involvement (reaction phenotyping). For most compounds, this process usually follows the Michaelis–Menten type of enzyme kinetics resulting in a hyperbolic rate of metabolite formation. However, for some compounds, an atypical kinetic profile may be observed, for example, sigmoidal, biphasic, or substrate inhibition kinetics. Regardless, the proper kinetic equation must be used to describe the kinetics and obtain the most accurate kinetic parameters. These estimated parameters are then used for *in vitro*–*in vivo* correlation (IVIVC) analyses to predict the human *in vivo* pharmacokinetics and the doses to be used in phase I clinical trials.

9.2 BACKGROUND

The introduction of a new chemical entity to the market is a long and expensive process with many potential pitfalls [1]. An integral component of drug discovery and development is determination of the enzymes catalyzing metabolism of the drug, the kinetics involved therein, and the resulting metabolic products. Previously, most of these efforts were focused on the cytochrome P450 (P450 or CYP) enzymes, the primary enzymes involved in oxidative metabolism. However, as drug discovery efforts were focused on reducing P450-mediated metabolism, other enzyme families such as the glucuronosyl transferases (UGTs), the sulfotransferases (SULTs), the flavin monooxygenases (FMOs), gained importance, resulting in efforts to determine the kinetics of these enzymatic reactions, as well. The kinetics of metabolizing enzyme reactions contributes to the half-life of a drug and its elimination rate, thus affecting the dosing regimen and potentially the route of administration. In addition, the resulting metabolic products are not always inactive or innocuous, potentially resulting in toxicity or other adverse effects. Thus, the proper identification of the enzymes involved in metabolism of a drug, the resulting metabolic products, and the kinetics of these processes is paramount to successful drug development.

This chapter summarizes the current state of knowledge in enzyme kinetics, including both typical and atypical enzyme kinetics. Also included is a discussion of the various *in vitro* systems employed to determine enzyme kinetic rates and the resulting products, as well as the strengths and weaknesses of each system. Finally, methods of determining kinetics with the intent of estimating *in vivo* clearances are discussed, as are the basics of enzyme inhibition.

9.3 IN VITRO SYSTEMS TO STUDY ENZYME KINETICS

There are three well-established systems to study P450 kinetics (microsomes, hepatocytes, and expressed enzymes), as well as a newly developed cell line, HepaRG, that is being tested for suitability to study drug-metabolizing enzyme kinetics. Each of these systems offers unique advantages and disadvantages for conducting *in vitro* determinations of enzyme involvement and kinetics of reactions. In fact, one usually employs a complement of the various systems to maximize the information gained, while optimizing the use of resources and reducing overall time to derive the desired information.

9.3.1 Human Liver Microsomes (HLMs)

The most commonly used system for determining drug-metabolizing enzyme kinetics are human liver microsomes (HLMs), prepared from human livers. In this case, the endoplasmic reticulum fraction is isolated from human liver tissue, typically obtained from tissue that was deemed nontransplantable. This system retains all the P450s as well as other microsomal enzymes such as the UGTs and FMOs [2]. Obviously, microsomes may be prepared from any animal species, permitting study of metabolism in that species. HLMs are relatively easy to prepare, convenient to use, can be stored frozen (-80°C) for long periods of time with little relative loss of activity, and are comparatively less expensive than other systems. Because they can be prepared in

relatively large quantities and then stored frozen, the same “batch” can be used for an extended period of time, allowing direct comparison of results conducted over time. It is relatively common for investigators to create a “master mix” of HLMs, pooled from multiple donors. Frequently, proportions of HLMs from various donor livers, wherein the relative activity of various P450 enzymes has been characterized are mixed to create a “master mix” with known isoform activity levels assumed to be representative of the population at large (in contrast to representing only a single individual). These pooled HLMs also avoid the potential use of a prep from an individual liver that might be deficient in metabolism by a particular isoform due to genetic polymorphisms that might provide misleading results.

HLMs offer additional advantages, including the fact that the enzymes are also anchored in the lipid membranes as they would be anchored in the liver *in vivo*. With respect to the P450s, HLMs also contain the redox partners cytochrome P450 reductase (CPR) and cytochrome *b*₅ (*b*₅) at physiologically relevant concentrations. Finally, all the drug-metabolizing enzymes that are present in HLMs are in physiologically relevant ratios, which is important in that *in vitro* data suggest that protein–protein interactions may occur that can alter enzymatic activity, and are dependent on ratios of the enzymes involved. To use HLMs, one simply adds a physiological pH (7.4) maintaining buffer, the enzyme cofactor nicotinamide adenine dinucleotide phosphate (NADPH), and substrate [3,4]. Since multiple enzyme isoforms are present in the preparation, determining the individual isoform(s) involved may be somewhat less straightforward but can be accomplished by coincubation with isoform-specific inhibitors or antibodies [5].

As with any system, there are also disadvantages to the use of HLMs for determining enzyme activity and isoform involvement. Depending on the time between tissue harvest, microsome preparation, and freezing, enzyme activity can be lost to varying degrees depending on the time duration. Freezing whole liver tissue first, then thawing and preparing HLMs can also reduce enzyme activity. In addition, once thawed for use, HLM preparations usually only maintain consistent activity levels for up to 1 h at 37°C, the usual temperature for conducting *in vitro* HLM incubations. It should also be realized that HLMs will not contain either cytosolic enzymes (e.g., SULTs) or transporter proteins [e.g., P-glycoprotein (PgP)]. This lack of the total complement of enzymes precludes evaluation of “total” metabolism of a compound if multiple enzyme families are involved. However, since both UGT and P450 enzymes are present in HLMs, one can add the necessary cofactors for both to permit simultaneous activity by both enzyme systems and thus, to evaluate the overall metabolism by both systems, though this requires care in determining the incubation conditions. More typically, each route of metabolism is evaluated separately. Finally, it should be realized that HLM preps do not contain the necessary machinery for enzyme synthesis and thus, cannot be used for enzyme induction experiments. In spite of these limitations, HLMs remain the primary “workhorse” of drug metabolism studies, given their relatively low cost, ease of use, and availability.

While study on CYPs in HLMs essentially only requires NADPH as a cofactor and an appropriate buffer, the study on UGTs require more involved conditions. Like with the CYPs, a cofactor, uridine-5′-diphosphoglucuronic acid (UDPGA), that provides the glucuronic acid for transfer also needs to be included [6]. However, in contrast to the CYPs, since UGT proteins exist with their active side facing the luminal part of the endoplasmic reticulum, access to substrates and cofactors requires them to pass

through the membrane to access the active enzyme site. Hence, membrane disruptors such as alamethicin (pore-forming agent), sonication, or use of a surfactant (e.g., Brij 58) are required to obtain activities that are readily measurable. Disruption of the membrane is usually conducted on ice for a period of 15–30 min before beginning incubation with substrate. Saccharolactone, a β -glucuronidase inhibitor is sometimes also added to prevent an artificial lowering of UGT activity [7]. Finally, recent research has suggested that a number of K_m values generated earlier may have been artificially elevated due to the presence of inhibitory long-chain unsaturated fatty acids in the incubations that can compete with substrates for the UGT active site. However, it appears that the inclusion of albumin can restore K_m to values that result in more accurate IVIVC predictions. Thus, some researchers advocate for the inclusion of albumin in all incubations evaluating UGTs; however, this opinion is not shared by all.

FMOs are a microsomal enzyme that can metabolize soft nucleophiles, such as nitrogen- and sulfur-containing compounds and, in particular, heterocycles with these atoms. Since FMOs can catalyze analogous reactions to the CYPs, such as N- and S-oxidation, it is important to distinguish between the two enzyme families to assure the correct implications are made. The incubation conditions for FMOs are the same as CYPs, that is, it requires substrate, NADPH, and buffer but at a slightly alkaline pH of 8–9 for optimal activity. To distinguish between CYP and FMO metabolism, the microsomal mixture can be incubated at 45°C for 5 min in the absence of NADPH, causing degradation of the FMOs but leaving the CYPs unaffected. The reaction is then carried out under normal conditions and if the activity goes away, the implication is that FMOs were involved since they would have been degraded during the preincubation. Nonionic detergents that inhibit CYPs but not FMOs can also be used to delineate between the two enzyme families.

9.3.2 Expressed Enzymes

With current technology, almost any individual P450 isoform human or animal cDNA can be expressed in cell systems, such as *Escherichia coli* bacteria, yeast, or insect cells (e.g., *Trichoplusia*), and the resulting enzymes can subsequently either be fully purified or membrane preps can be generated [8,9]. In addition, CPR or b5 can be coexpressed in these cells (with membrane preps as the final form) [10,11]. The enzymes thus obtained are suitable to determine kinetics of a substrate from a single P450, assuming that the cDNA from only a single enzyme was expressed. Expressed enzymes are the simplest system and can provide unequivocal evidence of the ability (or lack of ability) of an enzyme to metabolize a substrate. Expressed enzymes also allow for discernment of the reaction kinetics of a single enzyme, which may be confounded by multiple enzyme involvement in systems with the full enzyme complement. Expressed enzymes offer additional advantages that make them an attractive system in certain circumstances. For example, because only one enzyme is present, they can be used to identify isoforms that make a minor contribution to the metabolism of a substrate that might become more important when the primary isoform is inhibited [12]. This situation would be difficult to discern in a system with the full complement of enzymes that might overshadow this contribution by a more minor enzyme. Hence, expressed enzymes can provide comprehensive information on all the isoforms metabolizing a substrate. In addition, atypical kinetics (see below) are also most accurately elucidated using single enzyme systems, since confounding may occur in multiple enzyme systems

[3]. Finally, expressed systems allow the most convenient study of the kinetics of polymorphic enzymes, since allelic variants are easily expressed in sufficient quantities in these systems. Locating and genotyping sufficient quantities of, for example, HLMs, expressing an allelic variant, is currently difficult.

Incubations using expressed enzymes are, as with microsomes, a straightforward affair with only the addition of an appropriate cofactor [such as NADPH for P450s, 3'-phosphoadenosine-5'-phosphosulfate (PAPS) for the SULTs, and UDPGA for UGTs], buffer at pH 7.4 and the substrate being required. These systems are generally robust enough to provide activity for up to 45 min with a subsequent drop in activity and also hardy enough to withstand a few freeze thaw cycles. Expressed enzyme preparations of CYPs, UGTs, *N*-acetyltransferases (NATs), FMOs, aldehyde oxidases (AOs), SULTs, monoamine oxidases, and esterases are now commercially available and are valuable tools in reaction phenotyping and metabolic pathway elucidation.

It should be realized that expressed enzymes also possess certain disadvantages. For example, since they do not contain the full complement of enzymes, overall clearance is more difficult to estimate and the relative importance of individual enzymes may be overestimated. The fact that a substrate is metabolized by an enzyme in a single-enzyme system does not indicate that this will be observed *in vivo* since a number of variables such as enzyme ratios, ratios of redox transfer proteins (see below), and unbound substrate concentrations at the enzyme active site can influence the metabolism. Also, the concentrations of CPR and b5 used in the expressed enzyme systems are designed for maximal activity and are not reflective of physiological levels. In addition, for fully purified enzymes, lipid vesicles (typically prepared from dilauroylphosphatidylcholine or didecanoylphosphatidylcholine) need to be added to the system as an artificial membrane system to provide a milieu for the hydrophobic portions of the enzyme to anchor. This again is an artificial system and may not be fully representative of complex *in vivo* architecture and interactions. These kinds of systems are termed *reconstituted expressed enzymes*, as opposed to expressed systems, wherein the enzyme is maintained in the membrane environment of the cell system.

A reconstituted recombinant enzyme incubation requires the expressed CYP enzyme, lipid vesicles, appropriate level of CPR (2:1 or greater CPR:P450), b5 (1:1 or greater b5:P450), reaction buffer at pH 7.4, and NADPH, all maintained at 37°C. Since this incubation typically requires a greater number of constituents to be mixed as compared with HLMs, there is typically greater variability in kinetic parameters depending on ratios, order of addition, type of lipids used, and so on. In addition, some P450s such as CYP3A4 are more challenging to reconstitute into lipids and elicit activity, as opposed to others such as CYP2C9 and CYP2D6. Clearance predictions can be made from expressed enzymes, but this usually requires incorporation of a relative activity factor (RAF) established using probe substrates of the enzyme to standardize the activity of the P450 isoform to microsomal activity and an accounting for the relative ratios of each enzyme in a typical liver system [13].

Recently, the issue of CYP enzyme protein-protein interactions has been discussed [14,15] adding an additional layer of potential complexity. In these cases, the presence of a second CYP isoform can modulate (either increase or decrease) the activity of the second isoform. Since expressed enzyme systems typically involve the incubation of a single CYP isoform, one would not expect these interactions to occur in this type of system. However, if these do occur in HLMs, conjectured but not conclusively

proven, then the *in vitro*–*in vivo* extrapolations made from expressed enzyme systems involving a single isoforms may be less accurate than anticipated. A second potential complication can occur when expressed enzymes are mixed in a cocktail fashion for studying enzyme involvement and inhibition interactions, since these protein–protein interactions may then occur in these expressed enzyme incubations containing more than one CYP isoform.

9.3.3 Human Hepatocytes (Fresh and Cryopreserved)

Human hepatocytes contain the entire complement of drug-metabolizing enzymes, induction machinery, and most transporters [16,17]. They also contain all the cofactors and other redox proteins in appropriate levels [18]. Thus, they provide a system very similar to an actual human liver (with the exceptions of blood flow and intercellular interactions). They can be used for longer (e.g., 8–10 h) experiments and hence, may be more beneficial in the study of slowly cleared substrates, though it should be realized that the activity of hepatocytes does decline with time [19,20]. A significant advantage of human hepatocytes (either fresh or cryopreserved) is their ability to synthesize new enzyme protein and thus, they are ideally suited for enzyme induction experiments. The second primary advantage of human hepatocytes is that they contain the full complement of enzymes and transporters and thus, are ideally suited to evaluate total clearance by metabolism and transport. However, this may also be a disadvantage if one wishes to identify the specific isoform(s) involved in metabolism or the kinetics of an individual process.

Fresh hepatocytes, isolated from donor livers, can be maintained in appropriate media and be utilized to determine enzyme kinetics. However, fresh hepatocytes are less readily available, more difficult to maintain than, for example, HLMS. They are also expensive and need to be used relatively soon after donor harvest and preparation [21,22]. Because this timeframe from harvest to preparation and final use can be variable in length, it is not uncommon to observe substantial intersubject variability. Additionally, it should be realized that since hepatocytes are obtained from recently deceased donors, liver function may have been compromised and multiple drugs may have been present at harvest. This could lead to induction or inhibition of the metabolizing enzymes. The extensive handling procedures and expensive materials cost offset some of the advantages of using fresh hepatocytes. Cryopreserved hepatocytes were developed to overcome some of the disadvantages of freshly isolated hepatocytes. These hepatocytes are cryogenically frozen and thus, can be stored for long periods before use, making them more attractive than fresh hepatocytes that typically need to be used within a few days of extraction [23,24]. Cryopreserved hepatocytes can also be pooled, as is done with microsomes, to reduce the impact of interindividual variation. Though originally less active, recent advances in preparation and preservation techniques have resulted in cryopreserved hepatocyte preparations with activity similar to freshly isolated hepatocytes [23].

Incubations with cryopreserved hepatocytes have been standardized by suppliers of these tissues. Thawing and reconstitution of these cells, followed by incubation with buffer and substrate is the typical protocol. Fresh hepatocytes do not require the thawing and reconstitution steps that are required of cryopreserved hepatocytes, but may require additional Percoll filtration steps to improve viability. Since hepatocytes

contain all the necessary cofactors and additional proteins, no additional components need to be added to the media, although these incubations are typically done in 5% CO₂ at 37°C. Recent reports also suggest that cryopreserved hepatocytes, due to the process of instant freezing, are better suited for the study of AO activities that tend to be lost in fresh hepatocytes within 24 h post isolation [25].

9.3.4 Liver Slices

Liver slices are prepared from liver tissue using a microtome to create ultrathin slices. They contain all the drug-metabolizing enzymes and transporters, allow for intercellular communication, and in addition the role of passive diffusion can be elucidated [26,27]. However, liver slices exhibit a rapid decrease in activity (and typically activity lower than hepatocytes), are subject to interslice variation, cannot be pooled to overcome interindividual variation, are expensive to produce, and require special equipment to produce [28]. For these reasons, liver slices are not frequently used in kinetics determination.

9.3.5 S9 Fraction

The S9 fraction, such as microsomes, is prepared by homogenization of the tissue followed by ultracentrifugation to isolate the desired fraction. In this case, the S9 fraction is the supernate typically resulting from the spin before the 100,000g spin that is used to isolate the microsomes. Thus, this fraction of tissue will also contain the cytosolic and mitochondrial enzymes, though the activity can be lower than that of the microsomal fraction [29]. The presence of cytosolic conjugative enzymes such as SULTs, NATs, AO, and xanthine oxidases make the S9 fraction a more versatile system than microsomes. Though at one time used to measure overall metabolism, the requirement to add necessary cofactors and the availability of human hepatocytes has reduced the use of S9 fractions in determining enzyme kinetics and drug metabolism reactions. Incubation conditions for S9 fractions are similar to those with microsomes, that is, substrate, buffer, and appropriate cofactor need to be added. Typically, higher concentrations of protein, 2–4 mg/mL final, are used due to the inherent diluted nature of this system.

AOs are being increasingly recognized for their role in drug disposition, are a cytosolic enzyme, and hence found in S9 and cytosolic fractions and hepatocytes [30]. Their use does not require any special incubation conditions apart from enzyme, substrate, buffer, and recognition. Esterases are present ubiquitously, and hence, any tissue fraction, be it microsomes, cytosol, or a tissue homogenate, can be used to determine the esterase activity and substrate specificity. No unique cofactors are required to be added for esterase activity.

In contrast to the above cytosolic enzymes, the SULTs, another cytosolic drug-metabolizing enzyme, require addition of the cofactor PAPS to supply the sulfate group that is transferred onto the phenolic oxygen during an SN₂ substitution reaction. Similarly, NATs can be assayed for activity in cytosolic protein or S9 at protein concentrations of 0.2–1 mg/mL, 1 mM ethylenediaminetetraacetic acid (EDTA), dithiothreitol (1 mM; optional), phosphate buffer, pH 7.4, and acetyl CoA (2 mM). Acetyl CoA is the cofactor supplying the acetyl group that is added onto a nitrogen atom.

9.3.6 HepaRG Cells

The HepaRG cell line was created following immortalization of liver cells from a donor with hepatocellular carcinoma [31]. The cells were subsequently cultured and passaged with the cells then differentiated by the addition of dimethyl sulfoxide (DMSO). Once DMSO is added to the medium, the cells differentiate into hepatocyte-like granular cells with one or two nuclei. In addition, during this process, bile cannicular-like structures are formed [32]. As compared with isolated human hepatocytes, HepaRG cells exhibit comparable or greater levels of many drug-metabolizing enzymes (CYP1A2, CYP2B6, CYP2C9, CYP2E1, and CYP3A4, SULTs, UGTs, and glutathione-S-transferases), transporters, and induction elements (constitutive androstane receptor, peroxisome proliferator-activated receptors, aryl hydrocarbon receptor, and pregnane X receptor) [33,34]. In addition, the bile cannicular-like structures provide another level of detail and physiology to these cells [35,36]. Endogenous proteins such as albumin, haptoglobin, and aldolase B are also present in these cells [34]. Together, these factors suggest that HepaRG cells are very similar in morphology and physiology to liver cells, making them an appropriate system to study enzyme kinetics, inhibition, induction, and long-term toxicity. In addition, the HepaRG cells are stable for up to two weeks after differentiation and hence are useful to study slowly metabolized substrates, as well as conduct long-term toxicity and mutagenicity studies.

However, there are some identified disadvantages of HepaRG cell lines. For example, at the present time, they do not contain all P450s at physiologically appropriate ratios—for example, CYP2D6 is not present since the donor may have been a CYP2D6 poor metabolizer [34]. In addition, since it is a cell culture system, constant maintenance is required and sufficient time must be allowed (over 30 days) for the cell line to be cultured and differentiated. Despite these disadvantages, the HepaRG cell line appears to have promise toward providing qualitative and quantitative information on drug metabolism, although further characterization of activity and enzyme levels is required.

9.4 BASICS OF ENZYME KINETICS

9.4.1 Michaelis–Menten Kinetics

Enzyme kinetics are assumed to be governed by processes that are saturable and can be described mathematically by the Michaelis–Menten (Michaelis–Menten, sometimes called *Henri–Michaelis–Menten equation*) equation (Eq. 9.1), which states that at low concentrations of substrate, a first-order linear relationship exists between the rate and substrate concentration, and at high saturating concentrations of substrate, the rate is independent of substrate concentration and reaches a maximal value [37]. This maximal value is termed $V_{\max}$ or the maximum velocity, while half the concentration required to achieve this maximum velocity is termed K_m . With respect to the single-substrate reaction (Scheme 9.1), it should be realized that K_m is equal to $(k_{-1} + k_2)/k_1$ and thus is the amalgamation of several rate constants. With respect to affinity, unfortunately, K_m is frequently (and incorrectly) used interchangeably with K_S ($K_S = k_{-1}/k_1$), which is the substrate dissociation constant. Though K_m may sometimes approximate K_S when k_2 is very small relative to k_1 and k_{-1} , the two do not have to be equal, and numerous examples exist where these parameter values vary dramatically. $V_{\max}$ is

**Scheme 9.1**

indicative of the capacity of the enzyme to turnover that particular substrate, a higher $V_{\max}$ indicates faster turnover of substrate. The kinetic scheme and equation governing Michaelis–Menten equation are given as follows:

$$v = \frac{V_{\max} \cdot [S]}{K_m + [S]} \quad (9.1)$$

where $V_{\max} = k_2 \cdot [ES]$, which is a measure of the rate of product formation, $K_m = (k_{-1} + k_2)/k_1$ is the Michaelis constant, and $K_S = k_{-1}/k_1$ is the dissociation constant for the ES complex.

Figure 9.1a depicts the classic hyperbolic enzyme kinetics plot. Several assumptions have been made in the generation of the Michaelis–Menten equation. It is assumed that the $[ES]$ complex is in a quasi-steady state, that is, its rate of concentration change

Figure 9.1 Kinetics of enzymes following Michaelis–Menten (MM) kinetics: (a) the classic hyperbolic plot, (b) the Lineweaver–Burk (LB) double reciprocal plot, (c) the Eadie–Hofstee (EH) plot, and (d) the Hanes–Woolf plot. EH, LB, and EH plots can be used for determining whether the data follows MM kinetics, while all plots can be used for determination of the kinetic parameters— $V_{\max}$ and K_m .

is zero since each molecule of [ES] converted to product is replenished instantly. The other key assumption is that total enzyme concentration is constant and is the sum of free enzyme, [E], and the [ES] complex. Additionally, the concentration of the substrate is much higher than the enzyme, and this combined with the total enzyme concentration being constant implies that the rate has a pseudo-first-order dependence on substrate concentrations (at low nonsaturating substrate concentrations).

The Michaelis–Menten equation can be rewritten into a number of forms to allow for easier visual analysis of the data and calculation of kinetic parameters [37] (Fig. 9.1).

9.4.2 Lineweaver–Burk (LWB) Double Reciprocal Plot

$$\frac{1}{v} = \frac{K_m}{V_{\max}} \cdot \frac{1}{[S]} + \frac{1}{V_{\max}} \quad (9.2)$$

The Lineweaver–Burk (LWB) plot depicts the reciprocal of velocity versus substrate concentration and results in a straight line with a slope equal to $K_m/V_{\max}$, a y -intercept representative of $1/V_{\max}$, and an x -intercept equal to $-1/K_m$ (Fig. 9.1b).

9.4.3 Eadie–Hofstee (EadieHofstee) Plot

$$v = -K_m \cdot \frac{v}{[S]} + V_{\max} \quad (9.3)$$

The Eadie–Hofstee (EadieHofstee) plot is graphically represented as v versus $v/[S]$ and results in a straight line with slope equal to $-K_m$, with the y -intercept representing $V_{\max}$ and the x -intercept equal to $V_{\max}/K_m$ (Fig. 9.1c).

9.4.4 Hanes–Woelf Plot

$$\frac{[S]}{v} = \frac{1}{V_{\max}}[S] + \frac{K_m}{V_{\max}} \quad (9.4)$$

In the Hanes–Woelf plot, where it is plotted as $[S]/v$ versus $[S]$, giving a straight line with a slope representative of $1/V_{\max}$, where the y -intercept is equal to $K_m/V_{\max}$ and the x -intercept is equal to $-K_m$ (Fig. 9.1d).

Though each of the above graphical representations can give quick estimations of the kinetic parameters K_m and $V_{\max}$, in general, nonlinear regression fitting of the data to the Michaelis–Menten model is preferred for more accurate estimations. These types of nonlinear regression fits have been made easier with the advent of inexpensive, readily available, and easy to use kinetic modeling programs.

The first step in determination of enzyme kinetics, viz $V_{\max}$ and K_m values, or depletion rate constants, is the verification of time and protein (enzyme concentration) linearity. One must assure that the proposed length of the incubations is not so long that metabolite formation rates are affected by enzyme degradation and that the conditions do not consume all cofactors, such as NADPH or too much substrate that could also affect metabolite formation rates. To accomplish assurance of linearity of time, one usually conducts incubations at 4–5 time points, typically ranging from 5

to 45 min. In the case of enzyme concentration, again, 4–5 protein concentrations are employed. With regard to substrate concentration, a concentration near the expected $V_{\max}$ or at least equal to the expected K_m should be employed. Finally, determination of enzyme kinetics is also based on the assumptions of rapid equilibrium and steady-state conditions. To this end, the investigator should assure that <10% substrate consumption occurs throughout the experiment to maintain steady-state conditions. Obviously, the above methodologies are dependent on the ability to measure the formation of metabolite, as the measurement of the amount of “product” formed.

9.4.5 Use of Substrate Depletion Methods to Determine Enzyme Kinetics

Early in the drug discovery process, it is desirable to obtain estimates of clearance rates for the molecule to assess its viability for further development, before metabolic pathways of drug removal have been determined, and before expending significant resources and time to synthesize metabolite(s). While the traditional methods of assuring time and protein linearity as well as steady-state kinetics for the determination of enzyme kinetics is preferred, many less labor-intensive methods also exist. Since K_m values are in general of greater interest in the drug development process than $V_{\max}$ values, determining K_m from a substrate disappearance $t_{1/2}$ assay has been described and the theoretical validation of the technique explained [38,39]. The first-order rate of degradation of substrate over a range of substrate concentrations is determined, and the inflection point of the plot of first-order rate versus substrate concentration can give a very reasonable approximation of K_m . It should be noted that determination of the substrate disappearance $t_{1/2}$ for the prediction of *in vivo* clearances should typically be done at substrate concentrations well below K_m to assure linearity. However, K_m values are generally not known for new chemical entities, and hence, in an attempt to assure substrate concentrations below K_m , typically $1\ \mu M$ substrate concentration is utilized.

P450 kinetics has been extensively studied and K_m values from submicromolar to millimolar range have been obtained. Compounds with submicromolar K_m values typically are good substrates and can sometimes display saturable metabolism *in vivo*. The observed range of K_m values for UGTs has been reviewed extensively by Kiang *et al.* [40]. While UGTs are in general considered to be high K_m reactions, a closer analysis reveals that a wide range of K_m values starting from single digit micromolar ($5\ \mu M$) up to millimolar levels have been observed. However, the bulk of K_m values observed for the UGTs are in the double digit micromolar range and above, suggesting that saturation kinetics will not be observed *in vivo* since drug concentrations seldom reach this range. Even with K_m values in the range of $5\ \mu M$, the risk of nonlinear kinetics (due to saturation of clearance) for the UGTs is less likely when only unbound concentrations of the drug is considered.

In the case of the FMOs, the reported K_m values are in a much tighter range, from around $2.5\ \mu M$ to approximately $60\ \mu M$ [41–49]. For AOs, a molybdoflavoprotein that prefers to oxidize carbons with low electron density (nitrogenous heterocycles) [50,51], the reported K_m values have ranged from $3.4\ \mu M$ to upward of $400\ \mu M$ [52–55]. As suggested from these reports, K_m values for the FMOs and AOs are rarely in the low single digit micromolar concentrations, and hence, a $1\ \mu M$ starting substrate concentration for $t_{1/2}$ determinations is appropriate for these enzymes. However, for

the sulfonyltransferases, the K_m values span a broader range ($0.5\ \mu M$ to $\sim 1\ mM$) [56–63], but generally are in the low micromolar range.

One should use the lowest possible protein concentration to minimize nonspecific protein binding and to be cognizant of incubation time as microsomes are generally stable for only 45–60 min [64]. Also, it should be realized that a minimum of 15–20% of the drug needs to be cleared to provide sufficient analytical resolution. In the case of slowly cleared substrates, large errors may be introduced due to difficulty in dissecting the rate of depletion of substrate from analytical error. Substrate depletion methods can be used to determine half-lives that are used in estimating intrinsic clearances [65] (see Section 9.6).

9.4.6 Caveats to be Considered in the Determination of Enzyme Kinetics

The effects of solvents on the activity of enzymes also require special consideration, since most drug candidates are nonpolar and require some solvent component for dissolution. Numerous studies have demonstrated that various organic solvents can either activate or inhibit different isoforms, depending on the substrate and enzyme source. For example, at concentration of 0.3%, methanol and acetonitrile had no effect on CYP1A1, CYP2D6, CYP2B6, and CYP2C9. However, at a concentration of 1%, methanol inhibited these same enzymes by 12–26% and acetonitrile inhibited CYP1A1, CYP2B6, CYP2A6, CYP3A4, CYP2C19, and CYP2D6 by 10–60%, depending on the isoform. In contrast, even at concentrations as low as 0.1%, DMSO inhibited CYP3A4, CYP2C19, and CYP2D6 by 15–25% [66]. Ideally, one should try to use <0.3% of methanol or acetonitrile to dissolve substrates, though when not feasible, one should use as little organic solvent and preferably <1%.

9.5 ATYPICAL ENZYME KINETICS

While Michaelis–Menten kinetics are the most commonly observed kinetics among the drug-metabolizing enzymes, there is a growing database of substrate–enzyme combinations that display atypical kinetics. These non-Michaelis–Menten kinetics have been observed most frequently in CYP3A4 and CYP2C9, and they have also been observed in CYP2D6, CYP1A2, and CYP1A1. In addition to P450s, SULTs, UGTs, and PgP, transporter proteins have also been observed to demonstrate atypical kinetics. The application of the Michaelis–Menten equation to substrate metabolism displaying atypical kinetic behavior may result in errors in the estimation of *in vitro* intrinsic clearance, which is subsequently used in the estimation of *in vivo* clearance. Atypical kinetics is generally believed to occur when two substrate molecules (either two molecules of the same substrate or two different substrates) are present in the active site simultaneously [67]. It should, however, be recognized that multiple conformers of the enzyme or enzyme dimers [68] have also been suggested to contribute to the occurrence of atypical kinetics.

The following sections describe the various kinds of atypical kinetics, the equations governing them, and the diagnostic plots to determine the nature of the kinetics [69–72]. While this chapter focuses predominantly on CYPs, it should be noted that SULTs, UGTs, and transporters also display atypical kinetics. These have been reviewed previously and hence are not dealt with here [73].

Figure 9.2 Biphasic kinetics. The inset shows the diagnostic EH plot for the same.

9.5.1 Biphasic Kinetics

Biphasic kinetics (Fig. 9.2) is observed when the metabolite formation rate appears to initially behave as if it would begin to saturate but instead continues to increase in a linear fashion, such as that occurring with the CYP2C9 substrate naproxen [67]. In this case, two molecules of the same substrate are present in the enzyme active site. One of the catalytic sites behaves as a low K_m and low V_{max} (high “affinity,” low capacity) site, while the other catalytic site behaves as a high K_m and a high V_{max} site (low “affinity,” high capacity). Hence, at low substrate concentrations, the first catalytic site is more represented in the velocity–substrate plot, while at higher substrate concentrations closer to K_{m2} , the second catalytic site is more prominent. As seen in Fig. 9.2, saturation is not observed, but a linear increase in velocity is observed at high substrate concentrations. The Eadie-Hofstee plot for this kind of kinetics is shown in Fig. 9.2 (inset). This type of plot will also be visible if two enzymes are present and both catalyze a single-substrate reaction, one enzyme with a low V_{max} and K_m and the other enzyme with a high V_{max} and K_m . When a substrate exhibits biphasic kinetics, but the Michaelis–Menten equation is incorrectly applied, an underprediction of clearance (V_{max}/K_m) typically occurs. When substrate depletion experiments are used to determine intrinsic clearance, one must be careful to use an appropriate substrate concentration (typically as low as possible, e.g., $1\ \mu M$ or lower) so as to best reflect metabolism at the low K_m site (which is typically nearer actual physiological concentrations of the drug), rather than a higher concentration that might reflect the high K_m site and typically not physiological.

The equation used to describe biphasic kinetics (Eq. 9.5) is as follows:

$$v = \frac{(V_{max1} \cdot [S]) + Cl_{int}^* [S]^2}{K_{m1} + [S]} \quad (9.5)$$

Figure 9.3 Autoactivation kinetics. The inset shows the diagnostic EH plot for the same.

where $V_{\max 1}$ and K_{m1} are the parameters governing the first catalytic site and Cl_{int2} is $(V_{\max 2}/K_{m2})$ for the second catalytic site, that is, Cl_{int2} is the slope of the linear portion of the plot that occurs at high substrate concentrations.

9.5.2 Autoactivation (Sigmoidal Kinetics)

Autoactivation (Fig. 9.3) occurs when a substrate activates its own metabolism, again presumably when two substrate molecules occupy the active site at the same time resulting in a sigmoidal kinetic profile [67]. Detecting sigmoidal kinetics can be challenging since the changes in the substrate–velocity plot at low substrate concentrations are often subtle, sometimes making it difficult visually to distinguish from Michaelis–Menten kinetics. Thus, it is suggested that the data be plotted in an Eadie-Hofstee plot (Fig. 9.3, inset) to better assess the type of kinetics being exhibited. It should be recognized that sufficient analytical sensitivity and precision are also paramount in establishing autoactivation kinetics. When autoactivation (sigmoidal) kinetics are observed in a two binding site model, $V_{\max 2} > V_{\max 1}$ (when $K_{m1} = K_{m2}$) or $V_{\max 1} = V_{\max 2}$ (when $K_{m2} < K_{m1}$) [67]. Hence, two independent solutions exist to the sigmoidal equation. The two binding sites can have naturally differing $V_{\max}$ and K_m values, or the binding of the first substrate molecule could cause a conformation change in the enzyme active site, thereby altering the $V_{\max}$ and K_m values of the second binding site. If the $V_{\max}$ and K_m values of the two binding sites are similar in values, then a hyperbolic profile will be visible. Use of the Michaelis–Menten equation to predict kinetic parameters for a substrate exhibiting autoactivation kinetics will result in an estimation of $V_{\max}$ and K_m more reflective of the high $V_{\max}$ site, most likely leading to an underestimation of intrinsic clearance at the more physiologically relevant concentrations that usually occur near K_m of the lower $V_{\max}$ site. In substrate depletion experiments, as with biphasic kinetics, the starting substrate concentration will determine whether the intrinsic clearance of the first or second catalytic site is estimated.

The Hill equation (given below) can be used for a simplistic fit of autoactivation data:

$$v = \frac{V_{\max} \cdot [S]^n}{K' + [S]^n} \quad (9.6)$$

where n is the degree of cooperativity; a value of n equal to unity represents no autoactivation, whereas a value of $n > 1$ suggests cooperativity and thus, sigmoidicity. Note that this equation gives the parameter K' , which is analogous to, but not the same as, K_m . If a sufficient number of data points are employed, one can use Equation 9.7 to estimate the $V_{\max}$ and K_m values for each of the two binding sites:

$$v = \frac{\frac{V_{\max 1} \cdot [S]}{K_{m1}} + \frac{V_{\max 2} \cdot [S]^2}{K_{m1} \cdot K_{m2}}}{1 + \frac{[S]}{K_{m1}} + \frac{[S]^2}{K_{m1} \cdot K_{m2}}} \quad (9.7)$$

where $V_{\max 1}$ and K_{m1} are the kinetic parameters for the first binding site and $V_{\max 2}$ and K_{m2} for the second binding site.

9.5.3 Heteroactivation

Heteroactivation occurs when coincubation with another molecule (effector) results in an increase in the metabolism of the primary substrate [67,74]. The effector molecule is frequently also a substrate for the same enzyme, but this is not an absolute requirement. Importantly, in the case of heteroactivation coincubation of substrate, the effector does not result in inhibition of the primary substrate, as might be expected. It is generally believed that as with the other atypical kinetics phenomena discussed herein, the effector and substrate are believed to be present in the active site simultaneously, despite the fact that they are different molecules. It should also be noted that effector molecules binding to an allosteric site outside the active site have been reported [75], possibly causing conformational changes within the active site that might result in cooperativity. It has also been observed that the effector molecule is capable of undergoing metabolism simultaneously with the substrate [10]. This suggests that both the effector and substrate are present simultaneously in the catalytic region of the enzyme [67,76]. The following equation has been used to describe data exhibiting heteroactivation kinetics:

$$v = \frac{V_{\max} \cdot [S]}{K_m \frac{\left(1 + \frac{[B]}{K_B}\right)}{\left(1 + \frac{\beta[B]}{\alpha K_B}\right)} + [S] \frac{\left(1 + \frac{[B]}{\alpha K_B}\right)}{\left(1 + \frac{\beta[B]}{\alpha K_B}\right)}} \quad (9.8)$$

where the parameter α is related to the change in K_m due to the presence of the effector ($\alpha < 1$ is reflective of a decrease in K_m), β represents change in $V_{\max}$ due to the presence of the effector ($\beta > 1$ is reflective of an increase in $V_{\max}$), $[B]$ is the effector concentration, and K_B is the dissociation constant of the effector.

Obviously, when determining the clearance of substrates *in vivo*, one does not include a second substrate molecule and so though $V_{\max}$ and K_m are affected by heteroactivation, it would not be operable in typical enzyme kinetics incubations. However, during *in vitro* drug–drug interaction exploration, heteroactivation can be problematic as it will be difficult to predict the degree of interaction that will occur *in vivo*. Studies have been conducted to determine whether heteroactivation occurs *in vivo*. *In vitro* studies demonstrated that diclofenac metabolism by CYP3A4 is stimulated in the presence of quinidine [77]. To assess whether this phenomenon also occurs *in vivo*, the metabolism of diclofenac in monkeys in the presence and absence of quinidine was studied and it was observed that an $\sim 57\%$ decrease in the plasma concentration of diclofenac was observed when quinidine was coadministered as compared with diclofenac alone [78]. In humans, demonstration of heteroactivation has been less clear. Hutzler *et al.* [79] were only able to demonstrate an $\sim 10\%$ activation of flurbiprofen metabolism by dapsone in humans, despite substantial heteroactivation occurring *in vitro*. Though not directly studied, Egnell *et al.* [80], using a meta-analysis from multiple studies, predicted based on modeling that the coadministration of felbamate resulted in a 20–47% increase in the ratio of carbamazepine-epoxide to carbamazepine plasma concentrations due to heteroactivation of CYP3A4-mediated carbamazepine metabolism. A recent study examined the heteroactivation of CYP3A4-mediated metabolism of the dye Nile Red with α -naphthoflavone as an activator [81]. α -Naphthoflavone affected the sequential kinetics of Nile Red and increased the catalytic efficiency of the secondary metabolite production at the expense of the primary metabolite. Another recent paper provides the closest biophysical evidence for a two-site model based on longitudinal T_1 NMR relaxation and docking studies on carbamazepine-mediated heteroactivation of midazolam metabolism by CYP3A4. Midazolam metabolism typically results in greater quantities of 1'-OH-midazolam compared with 4-OH-midazolam when incubated with CYP3A4. However, this ratio declines in the face of high midazolam concentrations or the presence of carbamazepine. The distances of protons at the site of metabolism as determined from the NMR studies were used in docking simulations to demonstrate that when a single molecule of midazolam is present in the active site of CYP3A4, the 1'-CH₃ position of the molecule is closer to the catalytic heme, hence leading to the production of more 1'-OH-midazolam as compared with 4-OH-midazolam. However, at higher midazolam concentrations and when midazolam and carbamazepine are coincubated, two midazolam molecules or one midazolam molecule and one carbamazepine molecule assume a stacked position within the active site. This is predicted to result in the 4'-position of midazolam being oriented closer to the active heme than the 1'-CH₃ position. This observation could explain the shift in ratios of 1'-OH-midazolam to 4-OH-midazolam on homo- or heteroactivation.

9.5.4 Substrate Inhibition

Substrate inhibition (Fig. 9.4) occurs when, at high concentrations of the substrate, the velocity of metabolite formation decreases [67]. Figure 9.4 (inset) depicts the Eadie-Hofstee plot for substrate inhibition. Substrate inhibition is also thought to occur due to the presence of two molecules of the same substrate in the active site simultaneously. In the case of non-overlapping binding sites, substrate inhibition is observed when $V_{\max 2} < V_{\max 1}$ (and $K_{m1} = K_{m2}$ or $K_{m1} > K_{m2}$). When K_m and $V_{\max}$ of both sites are similar, substrate inhibition can still occur if a substrate molecule binding to

Figure 9.4 Substrate inhibition kinetics. The inset shows the diagnostic EH plot for the same.

one site physically hinders binding to the other site. Substrate inhibition can also occur when the substrate molecule binding to the second binding site causes a change in conformation or efficiency of metabolism at the first binding site. In this scenario, the second binding site is unproductive. One must be careful in interpretation of substrate inhibition in that conditions forced on the system by the inclusion of high substrate concentrations can also cause conformational changes in the enzyme, affect electron transfer, stimulate ionic interactions, or shield ionic interactions, leading to the changes in substrate metabolism rate that mimic true substrate inhibition kinetics. It is unlikely that substrate inhibition will be observed *in vivo* due to the inability to reach the typically high substrate concentrations needed to observe the effect.

The following equation is used to describe data exhibiting substrate inhibition:

$$v = \frac{V_{\max}}{1 + \frac{K_m}{[S]} + \frac{[S]}{K_i}} \quad (9.9)$$

where K_i is the inhibition constant of the binding of the second molecule causing the inhibition. One should be careful to not confusion substrate inhibition with product inhibition, which can result in a similar kinetic profile. To do so, one must consider the amount of product formed and the inhibition constant for the product toward the reaction. In general, substrate inhibition is much more common than product inhibition.

9.5.5 Partial Inhibition

Partial inhibition occurs when saturating concentrations of an inhibitor are unable to completely inhibit metabolism of a substrate [70]. This phenomenon is usually indicative of mixed inhibition, wherein a productive enzyme-substrate-inhibitor complex is formed. This complex can continue to form product, hence accounting for the partial inhibition. The inhibitor can either bind to the protein in an allosteric site or in the catalytic pocket of the enzyme, resulting in either conformational changes or steric hindrance, thus affecting the binding and metabolism of the substrate.

9.5.6 Substrate-Dependent Inhibition

Because of the presence of multiple binding sites within an enzyme active site, the potential exists for two molecules that are substrates for the same enzyme to bind to the enzyme but not result in either inhibition or activation. This can result in substrate-dependent inhibition, wherein an inhibitor will inhibit the metabolism of one substrate for the enzyme (i.e., both inhibitor and substrate bind to the same site) but not inhibit the metabolism of another substrate for the same enzyme (i.e., the substrate and inhibitor bind to different sites within the enzyme active site). This is particularly problematic during *in vitro* assessment of drug interactions using a probe substrate. One may miss additional potential interactions with an enzyme when only a single probe substrate is used. In these cases (especially CYP3A4), one should employ at least two probe substrates that are thought to bind to different sites within the active site to best assure assessment of full interaction potential. Substrate-dependent inhibition has been observed for CYP2C9, CYP3A4, and CYP2D6, where K_i values have been found to differ by orders of magnitude depending on the substrate [82–85]. Recently, substrate-dependent inhibition of CYP2D6 was demonstrated, while also suggesting the occurrence of two-site inhibition, such as noncompetitive and uncompetitive inhibition. The observation of both noncompetitive and uncompetitive inhibition further substantiates the possibility that CYP active sites are large enough to accommodate multiple substrates simultaneously.

At least one instance of substrate-dependent inhibition *in vivo* has been reported [86]. Mibefradil (CYP3A4 substrate) coadministration increased triazolam area under the curve (AUC) ninefold, but isradipine (another CYP3A4 substrate) coadministration had a minimal effect on triazolam AUC. Hence, although all mibefradil, isradipine, and triazolam are substrates of CYP3A4, only mibefradil had an effect on triazolam disposition, demonstrating the occurrence of substrate-dependent inhibition in humans.

9.6 IN VITRO–IN VIVO CORRELATIONS

An important objective of drug discovery research is the determination of rate of removal of drug *in vivo* and the residence time of the drug in the body. The process of scaling up from *in vitro* systems to *in vivo* systems, commonly referred to as *IVIVCs*, was first developed by Rane *et al.* [87] and further refined by Houston [88] and later Obach *et al.* [65]. The clearance rate of a drug determines its rate of removal from the body. Clearance is defined as the volume of blood cleared of drug per unit time per unit body weight and includes drug removal mechanisms from the gut, liver, kidney, and other organs. To allow direct comparisons between the *in vitro* and *in vivo* situations, one typically estimates the intrinsic clearance (Cl'_{int}), which is the capacity to clear drug from blood in the absence of protein binding and blood flow restrictions. Intrinsic clearance (Eq. 9.10) has the units of the rate of removal of drug per unit concentration:

$$Cl'_{int} = \frac{v}{[S]} \quad (9.10)$$

As described previously, the Michaelis–Menten equation (Eq. 9.1) can be used to fit data that conform to a hyperbolic profile.

In vivo, the concentrations of substrate in the blood rarely approach K_m , such that the $[S]$ in the denominator can be eliminated and Equation 9.1 simplifies to the following:

$$v = \frac{V_{\max} \cdot [S]}{K_m} \quad (9.11)$$

Rearranging Equation 9.11 to place $[S]$ on the left-hand side of the equation makes it clear that the following equalities exist:

$$Cl'_{\text{int}} = \frac{v}{[S]} = \frac{V_{\max}}{K_m} \quad (9.12)$$

Such that the $V_{\max}/K_m$ determined from *in vitro* work serves as an approximation of Cl'_{int} , which can be related to the *in vivo* Cl'_{int} . As discussed above, this is predicated on the assumptions that there are no blood flow restrictions, rate is proportional to concentration, that is, the substrate concentrations are in the linear portion of the Michaelis–Menten equation, and there is no protein binding.

If multiple metabolites are formed, the velocities for the formation of all metabolites can be subsequently summed up to determine total intrinsic clearance:

$$Cl'_{\text{int}} = \sum \frac{V_{\max}}{K_m} \quad (9.13)$$

Early in drug discovery, the metabolic pathway(s) of drug removal has typically not been defined. In this case, the method of substrate depletion (see above) to determine half-life can also be applied to determine intrinsic clearances [65]. Since clearance is also defined as the rate of drug removal per unit time, it is analogous to the first-order rate constant ($k_{\text{elimination}}$). Assuming first-order linear kinetics, clearance is equal to the slope obtained from a velocity–substrate plot and can be related to half-life using the following equation:

$$Cl'_{\text{int}} = k_{\text{elimination}} = \left(\frac{0.693}{\text{in vitro } t_{1/2}} \right) \left(\frac{\text{mL incubation}}{\text{mg microsomes}} \right) \quad (9.14)$$

The clearance thus obtained is in units of mL/min/mg of microsomal protein. The substrate depletion method has also been validated to predict K_m [38]. This methodology has the particular advantage that the determination of K_m in this manner does not require knowledge of metabolites and pathway.

The intrinsic clearance, as obtained from above calculations, is then scaled up from microsomal quantities to a whole liver. This requires the use of a scaling factor that considers the typical amount of microsomal protein per gram of liver. Multiple values of microsomal protein per gram of liver have been used, ranging from 21 to 77 mg protein/g liver, although a value of 40 mg/g liver is the most widely used scaling factor [65,89]. A more recent review has advocated for the use of a scaling factor of 32 mg/g liver (29–34.4, 95% confidence interval) [90]. This intrinsic clearance can then be scaled from per gram of liver to an average liver weight per person (Eq. 9.15).

$$Cl'_{\text{int}} = \left(\frac{0.693}{\text{in vitro } t_{1/2}} \right) \left(\frac{\text{mL incubation}}{\text{mg microsomes}} \right) \left(\frac{45\text{-mg microsomes}}{\text{g liver}} \right) \left(\frac{20\text{-g liver}}{\text{kg body weight}} \right) \quad (9.15)$$

where the unit of intrinsic clearance is mL/min/kg.

In vitro incubations can also be performed with hepatocytes and as with microsomes, appropriate scaling factors have been developed. The number of hepatocytes per gram of liver has been reported to be between 99×10^6 cells/g of liver ($74\text{--}131 \times 10^6$ cells/g, 95% CI) [90] and 120×10^6 cells/g of liver [65] for use in scaling up to the whole liver. Expressed enzymes can also be used to determine intrinsic clearance, although as previously mentioned, there are disadvantages in using this approach since it might overestimate the contribution of the enzyme. A RAF is necessary to standardize the activity of each P450 isoform to its corresponding microsomal activity, which can then be scaled up [13]:

$$\text{RAF} = \frac{\text{Cl}'_{\text{int-HLM}}}{\text{Cl}'_{\text{int-recP450}}} \quad (9.16)$$

This factor needs to be determined for each isoform in the individual expressed enzyme preps using a specific probe substrate, for example, midazolam for CYP3A4, bufuranol for CYP2D6, phenacetin for CYP1A2, and diclofenac for CYP2C9 [13].

Since drugs can bind nonspecifically to proteins during *in vitro* incubations, it is necessary to account for protein binding in the determination of intrinsic clearances:

$$\text{Cl}'_{\text{int,u,inc}} = \left(\frac{0.693}{f_{\text{u,inc}} \cdot t_{1/2}} \right) \left(\frac{\text{mL incubation}}{\text{mg microsomes}} \right) \left(\frac{45\text{-mg microsomes}}{\text{g liver}} \right) \left(\frac{20\text{-g liver}}{\text{kg body weight}} \right) \quad (9.17)$$

where $f_{\text{u,inc}}$ is the fraction unbound drug in microsomes. When $V_{\text{max}}/K_{\text{m}}$ values are used to calculate intrinsic clearance, only the values of K_{m} need to be adjusted ($f_{\text{u,inc}}^* K_{\text{m}}$) since V_{max} values will be unaffected. Hepatic clearance (Cl_{H}) can then be estimated from intrinsic clearance using a hepatic model, such as the well-stirred model [91].

The equation for hepatic clearance using the well-stirred model is as follows:

$$\text{Cl}_{\text{H}} = \frac{Q \cdot \text{Cl}_{\text{int}}}{Q + \text{Cl}_{\text{int}}} \quad (9.18)$$

where Q is the blood flow to the liver estimated at 20 mL/min/kg for humans.

Incorporating both blood binding and protein binding of the drug, the equation takes the following form [13]:

$$\text{Cl}_{\text{H}} = \frac{Q \cdot f_{\text{u}} \frac{\text{Cl}'_{\text{int}}}{f_{\text{u(microsome)}}}}{Q + f_{\text{u}} \frac{\text{Cl}'_{\text{int}}}{f_{\text{u(microsome)}}}} \quad (9.19)$$

where f_{u} is the free fraction of the drug in blood and $f_{\text{u(microsome)}}$ is the free fraction in microsomes. Initial studies suggested that blood and microsomal binding may cancel each other out, but several subsequent studies have shown that the free concentration of the drug needs to be utilized in all clearance estimates [92]. A suite of 29 acidic, basic, and neutral compounds were tested for protein binding, and basic compounds exhibited

the greatest microsomal binding as compared with acidic and neutral compounds. In addition, for all compounds, inclusion of both plasma and microsomal binding resulted in the most accurate scale-up estimates [38]. Two reports have provided methodologies to empirically estimate protein binding of drugs in either microsomes or hepatocytes, providing an alternative to experimentally determining protein binding for each drug candidate [93,94].

These estimates of hepatic clearance are made using the assumption that the concentration of drug in the blood is equal to the concentration in the plasma. However, if the blood to plasma concentration ratio of the drug is different from unity, a correction needs to be included [65]:

$$Cl_{bl} = \frac{Cl_p}{B/P} \quad (9.20)$$

where Cl_{bl} is the blood clearance and B/P the blood to plasma concentration ratio of the drug.

It should be realized that the liver may not be the only organ responsible for clearing the drug. In this case, to determine the total clearance of the drug, one must sum (Eq. 9.21) the clearances from all organs involved in the clearance of the drug from the body, for example, excretory clearance from the kidneys and gut metabolism, though estimation of these individual clearances may not be straightforward:

$$Cl = Cl_{hepatic} + Cl_{renal} + Cl_{intestine} + Cl_{pulmonary} + \dots \quad (9.21)$$

Multiple studies have attempted to use the above IVIVC approach to evaluate the accuracy of predicting the hepatic clearance of a variety of drugs [64,65,92, 95–99]. In general, both microsomes and hepatocytes (fresh and cryopreserved) perform reasonably well in estimating *in vivo* clearance, although all systems tend to underpredict the clearance. Additionally, fresh and cryopreserved hepatocytes were equally proficient in generating clearance estimates for use in predicting *in vivo* clearance when both protein and plasma binding were considered.

9.7 CONCLUDING REMARKS

Determination of *in vitro* enzyme kinetics is critical to drug discovery and drug development. Utilization of the appropriate system and appropriate equations are important to avoid the generation of inaccurate estimates. Several *in vitro* systems (e.g., microsomes, hepatocytes, and expressed enzymes) can be used for this purpose. One must be cognizant of the potential for atypical kinetics and use appropriate kinetic models. When conducted properly, accurate estimates of *in vitro* kinetics can be used to successfully predict the pharmacokinetic properties of drugs, *in vivo*.

ABBREVIATIONS

AUC	Area under the Curve
b5	Cytochrome <i>b</i> ₅

CPR	Cytochrome P450 Reductase
DMSO	Dimethyl Sulfoxide
FMOs	Flavin Monooxygenases
HLC	Human Liver Cytosol
HLMs	Human Liver Microsomes
IVIVC	<i>In vitro</i> – <i>In Vivo</i> Correlations
NADPH	Nicotinamide Adenine Dinucleotide Phosphate
P450s	Cytochrome P450
PgP	P-Glycoprotein
RAF	Relative Activity Factor
SULTs	Sulfotransferases
UGTs	Glucuronosyltransferase

10.1 INTRODUCTION

Advances in molecular-based technologies and increased knowledge of genomics and proteomics have resulted in a greater understanding of the metabolic pathways and in particular, the polymorphisms that may cause less than optimal drug pharmacology, unexpected pharmacokinetics, and potential toxicities. The success of the Human Genome Project and improved *in vitro*–*in vivo* extrapolations, helping in the early attrition of potentially problematic drug candidates. These evaluations aid in the planning and design of clinical trials and selection of appropriate subjects for clinical therapies, particularly in oncology, and for drugs with a narrow therapeutic index. Cellular and subcellular fractions from specific organs including the liver, kidneys, and intestines are routinely utilized to assess metabolic and transporter influences on the bioavailability and pharmacokinetics of drug candidates. This chapter briefly describes systems used to understand the metabolic liability of drug candidates at the molecular level and reviews microarray analysis.

The nucleic acid arrays described in this chapter have a common origin in the DNA blotting methods pioneered by Southern in the early 1970s [1]. Majority of the current methodologies continue to use immobilized or tethered DNA or RNA that is hybridized with a second nucleic acid, and the unknown targets are identified by decoding hundreds of thousands of sequences in parallel analyses on a single sample and in a single assay. Direct comparisons of parallel tests on multiple samples (different tissues, individuals, or treatment groups) provide relevant data that can be used to assess the safety and efficacy of drug candidates and drugs.

In drug development, microarrays that can identify from tens to thousands of unique proteins or nucleic acid sequences are used to assess changes in levels of multiple proteins or transcripts after *in vitro* treatment over two or more days or *in vivo* treatments upward of one week. Arrays are typically printed on multiwell plates or glass slides with specific protein or DNA binding sequences that serve to capture target proteins or DNA. Samples from control and treatment cohorts can be compared to determine their gene profile parameters and potential differences due to treatment.

Data mined from the Human Genome Project for targets of therapeutic agents in combination with combinatorial chemistry improved structure–activity relationships and from high throughput screening have lowered later stage attrition of drug candidates and yielded candidates with a higher safety profile and improved efficacy. Owing to this, microarray technology has been incorporated into preclinical assessment programs to prioritize and further understand the potential liabilities of drug candidates early in the drug discovery and development [2]. Microarrays are also used to understand mechanisms of toxicity, identify biomarkers, and accurately diagnose tumor status based on gene expression alone. While these assays have many additional uses such as understanding coordination of biological pathways, this chapter focuses on measuring changes in gene expression to provide critical information regarding the pharmacokinetics, dynamics, metabolism, and safety profiles of compounds.

10.2 PROTEIN MICROARRAYS

10.2.1 Functional Analysis

Over the past decade, a variety of functional proteomics methods have been used to understand protein–protein interactions. Many of these assays are now conducted in high throughput, for example, the yeast two-hybrid assay [3,4], the protein complementation assay [5], affinity purification coupled with mass spectrometry [6,7], peptide phage display [8], oriented peptide library screening [9], and protein microarrays [10,11].

The yeast two-hybrid and protein complementation assays entail co-expressing a “bait” and “prey” protein in the same cell. If the two proteins interact, a reporter gene is expressed or a reporter protein becomes active. Major advantages of these assays are that they are conducted within living cells and no biochemical purification steps are required. The methods allow for efficient assessment of large numbers of potential interactions and have been used to conduct numerous genome-wide investigations [12–18]. Drawbacks of these techniques are that there is limited control over the assay conditions, integrity of the proteins cannot be assessed, and concentrations and posttranslational modification are difficult to determine and manipulate.

Methods based on affinity purification/mass spectrometry are powerful and compatible with genome-wide investigations [6,7,19]. The limitation is the restricted ability to control the environment or state of the interacting proteins. For these experiments, an epitope-tagged target protein is expressed in a cell of interest, where it interacts with endogenous proteins or complexes. Following affinity purification of the bait protein, interaction partners are identified by tandem mass spectrometry. This technique is well suited to identifying physiologically relevant complexes, making the choice of the type and state of the cells used important in defining the outcome. This assay works well when the interaction partners are highly expressed in the cells used but has the potential to provide false negatives for proteins that are not expressed or are present at low concentrations.

The methods described above provide primarily binary data, that is, proteins are reported either to “interact” or “not interact.” Genomic and proteomic investigations coupled with computational analyses would provide more predictive and reliable extrapolations if the data were quantitative and could be incorporated into predictive models of cellular behavior. Protein microarray technology can complement these approaches and provide a way to study protein–ligand interactions *in vitro* in a noncompetitive format.

In a typical protein microarray experiment, the target proteins are spotted in a regular pattern at high spatial density on a solid support, usually a chemically derivatized glass substrate or a glass-supported nitrocellulose membrane (Fig. 10.1). The spotted proteins become immobilized on the surface and are incubated with a labeled probe (e.g., a protein, peptide, nucleic acid, or small molecule). Then, protein–ligand interactions are identified using the label on the probe. For example, if the probe has been labeled with a fluorophore, the array is simply scanned for fluorescence. To date, this approach has been used primarily to investigate Src-homology 2 (SH2), phosphotyrosine binding (PTB), and PDZ-domain-containing proteins [20–22], many of which are critical to signaling in the liver. Going forward, investigations of other domain families (e.g., BH3-domain-containing protein, which are critical for mitochondrial apoptotic signaling, or RING-domain-containing proteins essential for ubiquitin-mediated protein degradation) will greatly enhance our understanding of fundamental liver biology.

Figure 10.1 Protein domains are immobilized on a solid support (glass substrate) and probed with solution-phase, fluorescently labeled peptides. After an incubation step, the arrays are washed and scanned for fluorescence. Spots comprising domains that recognize the peptide become fluorescent. Figure and related text are adapted from Kaushansky *et al.* Ref 11. (See color insert.)

10.2.2 Analysis of Changes in Cellular Signaling

Although protein domain microarrays provide valuable data with regard to molecular affinities and interactions that occur in a cell, a broader view of cellular pathways impacted by drug treatment, for example, is necessary. A number of new technologies have made analyses that were previously only possible by traditional Western blotting, possible on a smaller, more efficient scale. This is particularly useful in the context of analyses that require the testing of hepatocyte-derived samples since primary human hepatocytes are difficult and costly to obtain in large numbers.

Antibody microarray technology uses a very small amount of total cell lysate per measurement. In an antibody array, a wide variety of antibodies are attached to a glass slide and lysates, which have been modified to be labeled on either the N-terminus or the C-terminus with a fluorescent tag, are incubated with the slide. These arrays are commercially available and able to monitor differences among a wide range of signaling proteins. Alternatively, arrays can be fabricated from lysates. In a lysate microarray, each sample is printed on a glass slide coated with nitrocellulose. The slide is then treated similar to the membranes used in Western blots. Preliminary assessments of antibody microarrays are time and resource consuming, as it is critical to validate each antibody used for a particular cell line by comparing data obtained on control arrays to that obtained by Western immunoblotting. Although antibody validation is a challenge, the ability to obtain Western-blot-like information from a very small number of cells (thousands, instead of the millions used in Western blots) is a significant advantage and provides researchers with the capacity to monitor a large number of cellular signals at the protein level while using a small number of cells, such as primary hepatocytes.

10.2.3 Advantages of Protein Lysate Array Technologies in Absorption, Distribution, Metabolism, and Excretion (ADME)

Protein lysate and antibody array technology are viable options for assessing functionality of proteins expressed in tissues, such as the liver or kidneys, and molecular changes that take place on a protein level after perturbations to liver or renal biology (e.g., drug treatment). New technologies that allow for the monitoring of binding events and/or signaling changes with very small sample size allow for unparalleled insights into organ biology.

10.3 DNA MICROARRAYS

10.3.1 Background

The microarray was forged from the convergence of disparate technologies. Advances in the semiconductor industry have yielded “on-chip synthesis,” allowing for high density, *in situ* production of short oligonucleotide sequences that encompass individual probes from the genome. These oligonucleotide expression chip platforms may be produced with tens to tens of thousands of oligonucleotides, depending on the experimental design [23]. Another high throughput platform consists of spotting prefabricated polymerase chain reaction (PCR) products on a matrix [24]. Both platforms provide a stage by which sample RNA may be hybridized to the associated probe sequence and quantified to assess the functioning genome, also known as a *microarray expression analysis* [25].

In general, DNA-based microarrays are analysis tools that use nucleic acid fragments for the simultaneous and parallel examination of the changes in the levels of gene expression for individual genes and/or groups of related genes in response to environmental or biological factors. In addition, this array-based technology can assess individual genetic variations derived from polymorphisms, mutations, and genomic abnormalities associated with disease states [26–29].

Traditional solid-phase arrays use matrices made of materials such as glass, silicon, or membranes to which the nucleic acid probes are affixed. The hybridizing targets are RNA transcripts that are extracted from biological samples and converted to cDNA. In the dual color strategy, these are then converted to cDNA in conjunction with differing fluorescent labels of green (control sample) or red (test sample). The amount of labeled cDNA binding to a specific stabilized sequence is directly related to the intensity of the fluorescent signal. If the intensity of the red target is greater than the green target for a specific probe, then this indicates that the associated gene has been upregulated in the test sample as compared to the control sample. Yellow represents equal binding of the control and the sample, that is, labeled cDNA, and no change in gene expression [30–32]. Therefore, incorporation of dissimilar fluorescent dyes in the reference and experimental cDNA pools allows for differential gene expression analysis. Single color schemes provide absolute quantification of gene expression on a single matrix and may be more amenable to comparative studies that are temporally distinct [33]. In both scenarios, mRNA representing the steady-state balance between active transcriptional and degradation events within the biological source are embodied in the cDNA population [34], allowing for an expression pattern comparison of different genes among samples. Various detection methods, computational and integration software, and databases are available for subsequent data analysis and storage [35–39] and are detailed later in the chapter.

Limitations of gene expression microarrays include “noise” in the signal, leading to a higher than optimal background signal from the system. In some cases, regions of sequence homology can lead to target cross-hybridization, requiring additional confirmation using techniques such as Northern blots or S1 nuclease protection assays. Other causes of variation are the same as in all other systems, for example, human errors in pipetting, RNA extraction and labeling efficiency, microarray production, and differences in response to treatment among individual samples. Furthermore, posttranscriptional and posttranslational events necessary for appropriate gene expression are not captured.

Because of these potential complications, the microarray experimental setup should be guided by predetermined parameters and the actual design should be dictated by the questions that need to be answered. Ideally, biological and technical replicates should be included to account for variability and allow for distinction between background noise and actual signal, and data analysis and interpretation should be straightforward [40,41]. Technical replicates are useful in accounting for variations in sample preparation and labeling; biological replicates are necessary to address issues such as inherent basal variation between the reference samples. The distinction between biological and technical replicates can be somewhat vague and is determined to a great extent by sample size and availability. However, as the process progresses from starting sample to labeled sample to scanned image, background noise accumulates as a consequence of biological, biochemical, and physical effects. Standardized microarray methods can minimize technical variation, making biological variation the most relevant parameter

to be addressed [42]. In addition, these allow comparison of data from different platforms. Both cDNA- and oligonucleotide-based platforms have been used concurrently for mutual multiplexed verification and data integration using standardized methods [43,44].

10.3.2 Microarrays in ADME

Traditionally, microarrays have been used in drug discovery predominantly for therapeutic target identification and validation [45,46]. The data are used to follow the dynamic progression of disease states within a complex biological network and measure changes with drug exposure [47,48]. Literature is replete with examples of microarray gene expression studies that demonstrate the utility of microarrays in gene discovery programs. For example, much investigation has delineated gene expression signatures for tumor diagnosis, prognosis, or classification [49–52] and additionally, has explored drug response and drug resistance in tumors [53]. In fact, responses to a variety of drugs have been reported using microarrays, for example, 15 genes were found to be similarly involved and affected in cell growth, signaling, and trafficking in the cerebral cortex of mice chronically treated with lovastatin, pravastatin, and simvastatin [54]. Simvastatin modified expression of 23 genes in addition to those changed by all three drugs, including some involved in apoptosis. In another study, gene chip analysis of human duodenal biopsies and blood samples in subjects treated with valacyclovir was used to correlate drug pharmacokinetics with multiple intestinal genes [55]. The data from this study helped identify 4F2hc, an activator of the human oligopeptide transporter (HPT1), as being highly relevant to valacyclovir transport. Furthermore, microarray analysis was used to assess the changes in drug-metabolizing enzymes and transporters by the endothelin receptor-type A antagonist CI-1034 and the atherosclerosis drug avasimibe. Data revealed up- and down-regulation of several ADME genes, indicating the potential for multiple drug–drug interactions in the clinic [56,57]. More recently, the technique has been applied to determine individual variability in baseline expression of clinically relevant drug-metabolizing genes among a large population of human liver samples [58]. Establishing this foundation is crucial for the subsequent analysis of putative inductive and inhibitive roles of a potential drug compound.

Microarray analysis can be used to determine drug-mediated changes at the level of genes associated with absorption, distribution, metabolism, and excretion. Monitoring these global alterations in gene expression can help to predict potential drug interactions and cytotoxicity. Formats based on tissue or cell platforms are beneficial, but they are not necessarily amenable to an array design. Tissue arrays deal primarily with formalin-fixed, paraffin-embedded tissue blocks for testing antibodies against various normal tissue and tumor panels to screen antibodies, identify disease biomarkers, and assess antibody or biomarker specificity. These arrays are not used to assess activity. Cell arrays involve the creation of microfluidic devices or platforms of various cell types, such as bacterial, mammalian, and either transiently or stably transfected cells, for a range of cell-specific, gene-specific studies. The technology is not very applicable to or validated for ADME assays and does not offer a distinct advantage over the existing methods. Enzyme arrays can be performed in plates or slides and may use hydrogels or other biological matrices. For example, in oncological research, a protein array containing 170 breast cancers was profiled for 21 cytochrome P450 (CYP) enzymes to assess the expression profile of these proteins in breast cancer in order to

identify potential biomarkers and aid decisions regarding optimal adjuvant hormonal therapy [59]. For the most part, however, these protein arrays are not comprehensive or widely available for all enzymes and suffer from attenuation of enzyme activity when immobilized in gels or on a surface. In contrast, use of DNA microarrays is well established, and products are commercially available [35,37].

These assays can be an initial or adjunct screen to indicate which *in vitro* cell-based, gene-specific, or enzyme-specific assay should be performed to define the potential effects of drug treatment. The microarray results may be the first-line indicator of potential drug–drug interactions, particularly if the drug induces gene expression of multiple drug-metabolizing enzymes, nuclear xenobiotic receptors (NXRs), or transporters. These gene expression analyses can also be performed with quantitative polymerase chain reaction (qPCR) or reverse transcriptase polymerase chain reaction (RT-PCR). Microarrays simply permit the concurrent, convenient screening of one or more compounds against many targets. These arrays decrease assay time and generate a more complete assessment of possible off-target effects and potential for drug–drug interactions or adverse drug effects.

10.3.3 Biological Systems in ADME

Microarray advances are permitting high throughput and global transcriptome analysis of ADME-associated proteins and subsequent effects engendered by pharmaceutical agents. *In vivo* studies entail dosing animals with exogenous compounds and RNA extraction directly from the tissue to determine changes in transcriptional profiling. Well-characterized xenobiotics have been used to determine ADME gene expression patterns in rodents [60], and these correlate with existing data [34,61]. In addition, the effects of a compound may be compared to existing reference databases to define its ADME gene expression signature [62].

Laboratory rodent models are more genetically and environmentally uniform than human systems and do not include the intrinsic heterogeneity of the human population. In a study comparing transporter expression in 75 human donors with expression in 27 rhesus monkey donors [63], human transporter expression showed comparatively small variations when evaluated against human CYP3A4 transcripts. However, transporter variability was consistently lower in the monkey livers examined. A parallel study examining basal expression levels of other ADME genes demonstrated similar results, with higher variability in humans relative to the rhesus population [58]. Human gene expression data did not exhibit normal distribution patterns, indicating that the mean data could not illustrate the wide range of potential expression profiles.

Human hepatic cell lines have been used as the biological paradigm for measuring metabolic liabilities, as they have relatively limited variability [64–67]. However, these cell lines have functional disadvantages that include potentially aberrant nuclear receptor pathways, atypical metabolic enzyme expression, and inability to maintain other appropriate hepatocyte phenotypes [68,69]. The cell lines deviate phenotypically among laboratories and across passages [70], perhaps as an effect of differing culturing and subculturing conditions. Wilkening and Bader quantified gene expression of various drug-metabolizing enzymes during 10 consecutive intralaboratory passages of HepG2 cells and observed significant fluctuations in expression profiles with succeeding passage number [71]. The culturing environment was consistent at each passage. Therefore, the alterations were most likely due to inherent instability of the cell line.

Differences in drug-metabolizing activities have also been noted while monitoring within a single passage of HegG2 cells [71]. Similar modifications in nuclear receptor and transporter pathways are likely [72].

There is much greater variability among human individuals, and the quantitatively more limited variations in the cell lines do not represent the natural diversity of the human population. Primary human hepatocytes from different donor livers are the most acceptable model for determining the ADME properties of a drug candidate, and the resultant data have been shown to correlate with the *in vivo* human response. Use of multiple donors addresses potentially divergent individual responses to xenobiotics. Historically, catalytic enzyme activity has been the principal end point to detect induction instigated by a xenobiotic although mRNA has been shown to be a more sensitive assay that is not affected by potentially concomitant inhibition [73]. The U.S. food and drug administration (USFDA) has recently recognized this fact, and the 2012 drug interaction guidance recommends using mRNA analysis with three or more preparations of human hepatocytes as the end point for predicting interactions of drug-metabolizing enzymes and transporters. Extending customary PCR methods to microarray assessment of drug interactions in cultured hepatocytes creates a more complete profile for a drug candidate.

10.3.4 Strategy

The vast amount of data derived from a microarray analysis can be a bottleneck since commercial arrays can have thousands of genes. Investigation of the specific question of induction benefits from a simplified system that focuses only the relevant drug-metabolizing networks. Gene expression alterations in response to archetypal inducers have been examined reliably in cultured primary human hepatocytes using a platform with a condensed number of drug-metabolizing proteins, including some transporters [74]. Low density DNA microarrays have also been used effectively to validate the response to classic inducers in cultured cynomolgus monkey hepatocytes [75]. In addition, custom microarray slide chambers have been used to assess success of transporter inhibition mediated by small interfering RNA (siRNA) [76]. In this study, generated data were normalized to a control gene that expressed regularly across all samples, and fold change was determined by comparing the normalized values from treated and reference samples.

These types of custom microarrays in which all probe sequences are involved in drug metabolism, conjugation, or transport permit interrogation for both reported and unreported drug effects on gene expression and the investigation of coordinate regulation of gene expression following drug treatment. Since all genes on these microarrays are members of integrated regulatory gene expression pathways, these can serve as a marker or internal control for induction or suppression of gene expression as well as for drug selectivity or specificity in the modulation of gene expression (Fig. 10.2).

If the response is specific in this simplified system, then all members of the pathway should be affected. It can offer a measurement of potential off-target effects if multiple genes are affected or genes common to multiple pathways are affected. Furthermore, it permits the interrogation of expression levels for genes and pathways for which no *in vitro* or cell-based assay exists. The microarray format also lends itself quite easily to the analysis of multiple cell lines or hepatocyte lots versus a single drug or the analysis of multiple drugs versus a single cell line or hepatocyte lot, or tissues harvested from

Figure 10.2 Basal level ADME-associated gene expression in 22 untreated human hepatocyte lots. Total RNA isolated from 22 untreated cryopreserved human hepatocyte samples was labeled and hybridized to individual DTETM microarrays (NoAb BioDiscoveries, Mississauga, ON). Gene expression values represent the normalized, mean value (relative to a constitutively expressed control gene, GAPDH) from three individual microarray hybridizations ($n = 12$ for each gene). Fold change data was generated by comparing normalized gene expression levels between treated and untreated samples. *White squares* indicate the lowest level of fold change in gene expression ($<1\times$). *Black squares* indicate the highest level of fold change in gene expression ($>10\times$). Basal variations were noted among individuals. (See color insert.)

in vivo studies. A complete gene expression profile can be established for any combination of drug/cell line/hepatocyte lot and gene/regulatory pathway (Fig. 10.3).

10.3.5 Microarrays in Toxicogenomics

Toxicity is a complex interaction of a toxin and a biological system. When a toxin is delivered to the site of action, it interacts with a target molecule or alters the biological environment. This can cause cellular dysfunction and disrepair, resulting in toxicological response such as necrosis, cancer, fibrosis, or disease. The number of mechanisms by which a drug elicits a toxicological response is proportional to the number of mechanisms maintaining homeostasis, such as mitochondrial function, cellular activity, signal transduction, and gene expression. Therefore, monitoring a single marker to assess the toxicological response will neither accurately nor adequately predict a drug's toxicological mechanism. A holistic approach must be employed to capture the specifics of a complex process. To do so, Systems Toxicology integrates technologies and information from several “-omics” disciplines to profile a toxicological event [77]. One aspect is the monitoring of gene regulation in response to exposure to toxicants, known as *toxicogenomics*.

Toxicogenomics developed in the 1990s from the availability of genome-wide DNA sequencing and the converging technology of microarrays or “chips.” This allowed for measuring the expression levels of thousands of genes from the exposure to a toxicant. The sequencing of the genome powers microarray expression analysis with candidate oligonucleotide sequences covering multiple mechanisms, signal pathways, and polymorphic deviations that may influence a toxicant's response. The mRNA is quantified to form a transcript profile for a toxic insult. This in turn may be compared to similar profiles with known outcomes to better predict the toxicity potential of a test article and potential mechanism of action [78,79]. This is an oversimplification of the complexity in determining toxicity. Concentration, time course, species differences, target tissue, and target cells are a few of the variables that add to the layers of complexities in toxicogenomics. In addition, toxicogenomics cannot be viewed alone but needs to be integrated with other facets of toxicology, such as metabolomics, proteomics, pathology, biochemistry, and other disciplines, depending on the mechanism of action. This section will solely focus on the aspects associated with toxicogenomics.

10.3.6 Biological Systems in Toxicogenomics

In vivo studies have traditionally dominated toxicology. Preclinical evaluations on a rodent (typically rat) and a nonrodent species (in most cases, dog or monkey), followed by escalating dose studies in phase I clinical trials, are used to evaluate the safety profile of a drug candidate. The *in vivo* interactions among organs, tissues, and cells allow for a thorough investigation of the drug candidate in the preclinical species as tissues are harvested for biochemical, pathological, and mRNA analyses. A typical animal study consists of several dosing concentrations, including a vehicle control, to assess acute versus chronic toxicity over time [77], and observations are made on parameters such as weight, behavior, and organ function.

For toxicogenomic evaluations, biological samples are harvested and gene profile analysis is performed, comparing the dose time variables to the control treatment. The data are combined, and significant outcomes are recorded [80]. For example, brown

Figure 10.3 Induction of ADME-associated gene expression in six human hepatocyte lots treated with rifampicin for 24 h. Total RNA isolated from six human hepatocyte lots treated with either rifampicin (*rif*) or vehicle (*none*) were labeled and hybridized to individual DTE_xTM microarrays. Gene expression values represent the normalized, mean value (relative to a constitutively expressed control gene, GAPDH) from three individual microarray hybridizations ($n = 12$ for each gene). *White squares* indicate the lowest level of ADME-associated gene expression ($<1\times$) relative to GAPDH. *Black squares* indicate the highest level of ADME-associated gene expression ($>10\times$) relative to GAPDH. (See color insert.)

Norway rats were exposed to oral dosing of hexachlorobenzene, and microarray samples were prepared from blood, thymus, liver, spleen, and mesenteric lymph nodes [81]. Results indicated that the spleen and mesenteric lymph nodes exhibited significant changes for genes associated with granulocytes, chemokines, cytokines, and immunoglobulins [82]. A limitation of the preclinical evaluations is identifying the appropriate animal model, as these in many cases do not reflect the human response, particularly with regard to metabolites formed and toxicological responses. A large number of drugs fail in the clinic because of unexpected toxicities that were not observed in the preclinical species. In many cases, human *in vitro* systems better reflect, at least qualitatively, the clinical response. Furthermore, efforts have been put forth to limit animal testing and bridge the information gap using *in vitro* evaluations [83].

In vitro testing utilizes immortalized or transformed cell lines or primary cells as the biological source. Generally, homogeneous cell culture allows for a specific view into the interaction of a compound and a single cell type, such as using hepatocytes to study the potential for hepatotoxicity [84] or isolated CD4 T cells and B cells to assess immunotoxicity [31]. *In vitro* systems are amenable to efficient testing of complex regimens of concentration and time. Interspecies comparisons can be made under similar conditions in order to reduce experimental bias. In a paper presented by Kienhuis *et al.*, acetaminophen-induced hepatotoxicity in rat and human primary hepatocyte cultures was compared by using toxicogenomic data, as well as comparison of *in vitro* and *in vivo* rat data, from which relevant common pathways were identified [85]. However, *in vitro* systems have caveats, such as appropriate cell model and conditions and lack of support cells to retain *in vivo* function. Relying on a single cell type or even a mixed culture from a single organ may not provide the appropriate conditions in order to capture a toxic event. In the case of terfenadine, cardiotoxicity occurs when cardiomyocytes are exposed to high concentrations of the parental drug. Clinically, this may occur from an overdose of terfenadine or from inhibition of its intestinal CYP3A4-mediated metabolism, allowing accumulation in the blood to overdose levels. *In vitro* studies employing myocytes confirmed terfenadine effects on cardiotoxicity, while its metabolite terfenadine oxalate had no effect. A screen solely utilizing cardiomyocytes would implicate terfenadine as a cardiotoxin, as is the case; however, this would not account for the common clinical outcome of being safe because of metabolic clearance [86].

Conversely, cells lacking metabolic capacity may underestimate potential cytotoxicities when the metabolite is cytotoxic compared to its parental form. Therefore, cells retaining metabolic pathways may be required to accurately predict metabolically dependent cytotoxicity, as in the case of aflatoxin B1. When metabolically competent cells, such as primary hepatocytes or HepaRG, were employed, microarray analysis provided evidence supporting previously reported involvement of p53, as well as several novel genes FHIT, BCAS3, and SMYD3 in association with aflatoxin B1 genotoxicity [87].

Variations among cell systems and in the case of primary hepatocytes, among individual donors must be defined. Harris *et al.* [88] investigated three genotoxic hepatocarcinogens and one nongenotoxic hepatotoxin in primary hepatocytes from multiple donors and the HepG2 cell line. The results showed that both primary hepatocytes and HepG2 provided similar gene expression profiles; however, there were significant differences among the individual human donors. Although 2172 genes were modulated from all donors, individual donors expressed a portion of these. One donor expressed

only 29% of the affected genes, and 40% of the commonly identified genes were measured in all the donors. This illustrates the variation in idiosyncratic responses among humans and the difficulty extrapolating a single mechanism of action given the inherent variation. *In vitro* systems with appropriate constitutive activities must be vetted with *in vivo* responses within and between species to ensure clinical relevance and relevant extrapolations.

10.3.7 Bioinformatics

Toxicogenomic evaluations generate vast amounts of data since a DNA chip may have tens of thousands of individual genes, and multiple samples (time and dose-dependence) from different species add to the complexity. Bioinformatics has been very useful in melding statistics, computer science, database management, and analytical approaches in order to organize, visualize, and prioritize biological information [89]. The first line of analysis is to normalize the data to remove systematic bias and artifacts due to experimental conditions [31]. The resulting values are then processed for comparison among conditions or among experiments.

The standard approach for toxicogenomics studies is to determine which genes are differentially expressed, that is, which genes are induced or suppressed compared to the control. A common output is a tree-based visualization or heat map that is a graphic representation of a data matrix with a variable hierarchy of gene expression and associated sample. This tree is a simple representation of data for a single gene. It may be organized to bin up- or down-regulated genes in rank order by clustering the row vectors or relationships between samples by clustering the column vectors [32,90,91].

A statistical comparison of classes attempts to separate the gene expression into two or more groups according to specific exposure conditions. This is an effort to connect genes to an event. A *volcano plot* is a type of scatter plot made by graphing significance versus fold change [25]. The regions of interest are the points toward the top at the far right or far left of the graph. To visualize more complex relationships among multiple classes, Venn diagram may be employed to integrate the size of the information with cardinality of the sets and the intersection of their relationships [92,93].

In order to attempt mechanistic analysis, the abstract relationships among the data may be annotated by linking the genes with biological databases in order to include biological information such as proteomics, metabolomics, and phylogenetics. Together, the information may give insight into a gene's function, tissue expression, localization, and clinical ramifications from which signal transduction pathways may be identified or developmental-dependent phenotype is implicated [31].

Toxicogenomic databases provide a repository for gene expression as pathway and mechanistic information from both *in vitro* and *in vivo* testing. Toxicogenomic databases are available both commercially and as open access. The Chemical Effects in Biological Systems (CEBS) database maintained by the National Institute of Environmental Health Services (NIEHS) is "designed to display in the context of biology and study design, and to permit data integration across studies for novel meta-analysis" [94]. The EDGE database developed at the McArdle Laboratory for Cancer Research, University of Wisconsin (Madison, WI) is organized to address the differences in study design and platforms [90], while the Comparative Toxicogenomics database focuses

on cross-species comparative studies of gene expression [95]. From the “Minimum Information About Microarray Experiment (MIAME)” guidelines [31], a database was produced by the Functional Genomics Data Society (FGED) to advocate “for open access to genomic data sets” [96]. The Human Toxicogenomics Initiative (HTGI) consists of both public and private entities is working toward organizing this vast amount of data and publishing it in a public database [97].

10.4 SUMMARY

DNA microarray technology can be used efficiently to measure gene expression alterations with exposure to a compound, such as the xenobiotic induction of transporter and drug metabolism genes. Results obtained from these platforms correspond well to responses measured with activity and RT-PCR. Yet, the capability of simultaneous quantitation of many transcripts provides high throughput analysis of multiple end points. Custom cDNA microarrays can be used to examine the modulation of gene expression levels of a defined set of ADME-associated genes, focusing on the relevant proteins. Furthermore, the emphasis on transcript analysis for induction in the recent regulatory guidance creates higher relevance for these models and underscores the importance of microarrays in future drug discovery programs. Protein microarrays based on either purified proteins or cellular lysates allow for a more thorough and fundamental understanding of the signaling events that are at play during drug treatment. As these platforms are further developed, monitoring transcriptional as well as translational and posttranslational changes in response to drug treatment will become standard.

The widespread use of various microarray-based methodologies has also bolstered new disciplines, such as computational biology, bioinformatics, and toxicogenomics. More work on standardization is necessary to fulfill the expectations of toxicogenomics to adequately assess safety risks of drugs and chemicals. Standards for exposure assessment and hazard screening will need to be identified and implemented. This will require that the scientific community and policy regulators agree on acceptable screening methods, integrated databases, and reasonable decision trees. To move toward this end, variability in susceptibility of distinct populations must be determined as well as mechanistic information with clinical relevance. Given the historical reliance on animal studies, cross-species extrapolation will need to be refined and redefined in the context of gene expression and mechanism of action. Dose–response relationships may increase our understanding of low level exposures, as well as exposure to multiple therapeutics, chemicals, and behavioral influences, but will require validation with clinical outcomes. Little is known about the health impact of fetal and neonatal exposures and their effects, and this area still requires extensive work.

The microarray field has been moving toward standardization in assay design and data analysis. This will allow interpretation of results that can be understood in the context of preexisting data. As microarray tools become more sophisticated, the ability to incorporate and measure concurrent effects on multiple biological pathways will permit integration of entire networks in order to understand the global responses to a xenobiotic.

11.1 SUMMARY

Gastrointestinal tract, particularly the small intestine, is the site of absorption of orally ingested xenobiotics including nutrients and drugs. The objective of this absorption is the passage of these molecules from the intestinal lumen to the blood and/or to the lymphatic circulation. Moreover, the oral route is the major route used for administration of drugs since dosing is convenient and noninvasive and many drugs are well absorbed by gastrointestinal tract. It is therefore easy to understand that knowledge and the prediction of the passage of these molecules through the intestinal barrier are essential for the development of these compounds. The complexity of this barrier justifies the existence of many predictive models and explains the numerous studies done to develop and improve these patterns. This chapter provides an overview of key issues regarding the intestinal barrier, commonly used cell models and their weaknesses. Also proposed are an example of protocol for the use of model Caco-2 cells and a set of controls for validating the model.

11.2 INTRODUCTION

The intestinal barrier, in a general point of view, can be defined as the boundary between the intestinal contents and the internal medium of the human body, represented by the enteric circulation [1,2]. To be more precise, the intestinal barrier can be defined histologically, chemically, or metabolically.

11.2.1 Histological Point of View

The intestinal mucosa consists of a simple columnar epithelium, a lamina propria (collagen matrix containing blood and lymphatic vessels), and a muscularis mucosa [3]. The intestinal mucosa possesses villi, whose function is to increase the surface of absorption. The epithelium constitutes the essential element of the intestinal barrier and is composed of four major cell types: enterocytes (possessing microvilli, and implicated in the absorption), goblet cells (producing mucus), enteroendocrine cells, and Paneth cells [4]. Intestinal epithelium is a dynamic system continuously renewed from stem cells located in invaginations called *crypts of Lieberkuhn* [5]. The epithelial cells are connected by junctional complexes including adherens junctions, desmosome and especially tight junctions at the origin of the intestinal barrier impermeability.

11.2.2 Chemical Point of View

To reach the bloodstream, a molecule present in the intestinal lumen must cross several layers possessing specific physicochemical characteristics. Thus, the molecule will pass through the mucus layer (aqueous solution of mucin), the unstirred water layer (aqueous interface between the intestinal lumen and the plasma membrane), the lipid bilayer of the enterocytes plasma membrane, and the basement membrane associated with intestinal epithelium and reach the capillaries, then cross the basement membrane associated with the endothelium and the endothelium itself. All of these steps can limit the passage of a molecule.

11.2.3 Metabolical Point of View

If the liver is the organ of reference concerning the metabolism, the intestinal metabolism should not be underestimated. Indeed, the metabolic activity of the intestinal mucosa is the second largest of the human body after the liver. The metabolizing enzymes, such as aminopeptidases, dipeptidyl peptidase IV, esterase, sulfotransferase (SULT), UDP-glucuronyltransferase (UGT), glutathione-S-transferase (GST), cytochrome P450 (CYP) superfamily, and membrane transport systems, including P-glycoprotein (ABCB1), expressed by enterocytes, serve as a biochemical barrier [6]. Some works even seem to demonstrate that after normalization for the relative abundance of P450 enzymes in the organ, the metabolic activities of the intestine and liver are comparable. This ability to transform and/or to efflux molecules into the lumen of intestine is also a crucial element of the barrier intestinal.

The intestinal barrier is extremely complex and difficult to reproduce *in vitro*. There are many systems that attempt to mimic: organotypic models (everted gut sac, Ussing chamber), cellular models (cell lines: Caco-2, TC7, etc.), which all have advantages and limitations. The choice of one of them will depend mainly on the problematic of the molecules studied and resources available.

11.3 INTESTINAL METABOLISM

11.3.1 Longitudinal and Transverse Heterogeneities

The intestinal metabolism, in animals or humans, has been the subject of a very extensive work. Many difficulties have been encountered, leading sometimes to discordant results. Thus, one can be cited: (i) the low expression levels of intestinal metabolic enzymes relatively the liver; (ii) intra- or interspecies variability of expression of biotransformation enzymes; (iii) ethical and technical limitation for studies in humans; (iv) variability of sample preparation techniques; and (v) structural and functional heterogeneity of the intestine.

The human intestine is divided into two parts: the small intestine, subdivided into duodenum, jejunum, and ileum, and the colon. They differ in their histological structure and by their metabolism. Thus, when considering axially mouth rectum (longitudinal axis) of the gastrointestinal tract, the metabolic activity of the intestine is particularly highest in the upper part of the small intestine, with a maximum observed at the proximal jejunum [7]. It has been shown that the total P450 content increased slightly between the duodenum and the jejunum, then decreased markedly at the ileum. If this heterogeneous distribution concern phase I enzymes (i.e., CYP3A4, 2C9, or 2C19), phase II enzyme (i.e., GST, UDPGT) distribution is relatively homogeneous in small intestine but with a lower level of expression in the colon. These observations were consistent with the fact that absorption of most of the xenobiotics occurs in duodenum and proximal jejunum and with the fact that relative abundance of goblets cells increases from small intestine to colon. In the same way, the peptide transporter PepT1 (SLC15A1) appears to have higher expression in the duodenum than in the ileum [8]. However, the decrease of expression and/or activity, from duodenum to the colon, seems not to be associated with all membrane transport systems. Indeed, some reports has been demonstrated, by analyzing the rate of mRNA levels along the gastrointestinal tract, that expression of the drug efflux pump P-glycoprotein increases from the stomach to the colon [9], even if other studies have shown that the expression of P-glycoprotein is correlated with CYP3A4 distribution [10,11].

Another level of heterogeneity corresponds to crypt-villus axis (transverse axis) [7]. Three cellular phenomena are observed along this axis: proliferation, differentiation, and apoptosis. Proliferative cells (stem cells) reside in the crypts, while apoptotic cell are observed in the top of villi. Approximately three days after the terminal differentiation, the cells reach the villus apex, undergo apoptosis and are exfoliated in the intestinal lumen. In the crypts, stem cells generate four major differentiated cell types: enterocytes, goblet cells, and enteroendocrine cells, which migrate to the top of the villus, and Paneth cells that remain at the crypt [12,13]. The junction between the crypts and the villi is the limit from which the cells develop their specific characteristics. This organization is observed not only in the small intestine but also in the colon, except for a colon that has no villi or Paneth cells [14]. The differentiation gradient of enterocytes along the crypt-villus axis results in the existence of a gradient of expression and/or activity of metabolic enzymes. It was thus shown that microsomes prepared from crypts cells contained much less CYPs than microsomes prepared from the mature villus cells. The maximum activity was observed at the middle third of the villus. A similar gradient exists for phase II enzymes, especially for GST and UDPGT

[7,15]; P-glycoprotein is also highly expressed in villus cells but is barely detectable in crypt epithelium [16].

11.3.2 First-Pass Intestinal

The first-pass effect is defined as *partial* or *complete extraction* of the dose of a xenobiotic that takes place between administration site and the systemic circulation. Metabolism is a key element of this process. To reach the systemic circulation, a molecule, administered orally, must pass three potential sites of metabolism: the intestine, liver, and lung. To cross the intestinal barrier, a molecule can use the transcellular or the paracellular route [16]. Only molecules using the transcellular mode may be submitted to first-pass effect. During the cellular transfer, these compounds can undergo the action of phase I and phase II metabolic enzymes and can be expelled out of cells by membrane transport systems [17,18]. The first-pass effect is also facilitated by amplification systems of the intestinal luminal surface (i.e., valvulae conniventes, villi, microvilli) that allow a surface of absorption, and thus of potential metabolization, considerable. Despite the great variability of expression in humans, CYP3A enzymes, especially CYP3A4, are a key element of the intestinal first-pass effect [18–20]. These enzymes represent 80% of CYPs in the small intestine and about 50% of drugs are substrates for these enzymes. P-glycoprotein is another key element of the intestinal first-pass effect. This transporter belongs to the family of ATP-binding cassette (ABC) transporters and is present at the brush border of enterocytes. It is interesting to note that CYP3A4 and P-glycoprotein have many substrates in common and that their intestinal distributions may be correlated [10,11]. All these observations led to the hypothesis of coordinated actions between these two detoxifying proteins [21].

11.4 COMPARISON BETWEEN INTESTIN/Caco-2/TC7

11.4.1 Cellular Intestinal Model

Much attention is paid to the use of epithelial cell cultures for studies of drug transport mechanisms, especially during drug development in pharmaceutical companies. As the use of primary intestinal epithelial cells is limited by the rapid loss of their differentiated characteristics during culture, the attention has turned to the use of human established lines of tumor origin, which display a number of properties characteristic of differentiated intestinal cells with variable degrees of differentiation. Some of them, such as Caco-2, HT-29, and T84 cells have been shown to exhibit most of morphological and functional characteristics of enterocytes. Other cell lines, such as HCT8, HRT18, or SW1116, express only a partially intestinal differentiated phenotype [22]. The limitations of cell models must not be overlooked, but they offer the advantage of relative simplicity and are suitable for automated procedures. Caco-2 cells are the most used cellular model in studies on passage and transport. They were derived from a human colorectal adenocarcinoma. In culture, Caco-2 cells, despite their colonic origin, express the majority of the morphological and functional characteristics of small intestinal absorptive cells, including phase I and phase II enzymes and drug transporters; they differentiate spontaneously into polarized intestinal cells possessing an apical brush border and tight junctions between adjacent cells, and they express hydrolases and typical microvillar transporters.

Moreover, these cells, particularly Caco-2 cells, can be cultivated as monolayers of differentiated cells on a semipermeable membrane. Thus, separating the apical compartment from the basolateral compartment, which correspond to the intestinal lumen side and the serosal side, respectively, is possible. These cell lines, originated from tumors, are, however, out of the *in vivo* physiological environment; therefore, extrapolation of the data to the *in vivo* situation may be difficult; a similar conclusion can be otherwise drawn for most of *in vitro* culture systems.

11.4.2 Phase I Enzymes

Among the enzymes of phase I, CYPs have been the object of the largest number of studies [23–25]. There may be differences between these works, especially for those using human intestine as a model. These differences are related to techniques used (sample preparation, analytical techniques) and may also reflect human variability. Using enterocytes isolated from human small intestine, Zhang *et al.* have analyzed the expression of CYPs. The used technique allows the analysis of enterocytes from the villi without contamination by crypts cells. Several CYPs were detected at mRNA level: CYP1A1, 1B1, 2C, 2D6, 2E1, 3A4, and 3A5. In contrast, at the protein level, only CYP1A1, 2C, and 3A4 were detected. Other studies have demonstrated that CYP2C isoforms present in the intestine were 2C9 and 2C19 [23]. Regarding CYP3A5, it has been highlighted, at the protein level, in a small proportion of the caucasian population [26].

Despite the differences that may exist between the works, they agree that the main CYPs are those of the CYP3A family, especially the isoform 3A4. However, these CYPs are not or slightly (according to studies) expressed in Caco-2 cells [26–28]. Thus, Sun *et al.* [29], comparing the expression profile of many genes, including CYP3A4, have shown that Caco-2 cells expressed about 150 times less CYP3A4 the human duodenum. Treatment with 1 α ,25-dihydroxyvitamin D₃, an inducer of CYP3A4 at the mRNA level, and transfection of CYP3A4 cDNA are two ways for increasing CYP3A4 expression levels in Caco-2 cells [30,31]. However, expression levels do not reach the levels observed *in vivo*. Other CYPs have been highlighted in this cell line, at least at mRNA level, such as CYP1A1, 2E1, and 2B6. Caco-2 cells are widely used to study the passage of the intestinal barrier and is described in the literature as the reference model to study intestinal drug absorption. However, on the intestinal first-pass effect, due to the low expression of CYP3A4, it seems that these cells do not constitute a model of choice.

To overcome absence expression of CYP3A, the Caco-2 clone TC7 has been developed. This cell line, generated by passing Caco-2 cells 198 times, expresses CYP3A4 and 3A5 (at least at mRNA level) at a higher level than their parental counterparts. In addition, CYP3A4 is inducible by 1 α ,25-dihydroxyvitamin D₃ in this cell line. Moreover, several studies have demonstrated that TC7 cells are a good alternative to the Caco-2 parental line for drug transport studies [27,28,32].

11.4.3 Phase II Enzymes

The main phases II enzymes are present in the intestine, including UGT, SULT, acetyl-transferase (ACT), and GST [29,33–35] (Table 11.1). These enzymes are characterized by their large interindividual variations and their most important expressions in the

TABLE 11.1 Example of Phase II Metabolizing Enzyme Expressed in Human Small Intestine, Caco-2 Cells and TC7 Cells^a

	Small Intestine	Caco-2	TC7
GST	Alpha, mu, pi	A1, A2, A3, A4, O1, P1, T2, Z1	
UGT	1A1, 1A3, 1A4, 1A6, 1A7, 1A8, 1A10, 2B4 2B7, 2B15, 2B28, 2B17	1A1, 1A6, 1A9, 2B9	1A1, 1A3, 1A6, 2B7
SULT	1A1, 1A2, 1A3, 1B1, 1E1, 2A1	1A1, 1A2, 1A3, 1B1, 1C1, 1C2, 2A1	1A1, 1A2, 1A3, 1B1, 1C1, 1C2, 2A1, 1E1

^aRefs 29, 33–35, and 37–43.

small intestine compared to colon [36]. In the Caco-2 cells, at least at mRNA level, the GST class μ , π , and especially α (A1, A2, A3, and A4) has been highlighted [34,37]; UGT (especially after induction) such as the UGT 1A1, 1A6, 1A9, and 2B9; and SULT such as SULT 1A1, 1A2, 1A3, 1B1, 1C1, 1C2, or 2A1. From a general point of view, the activity of phase II enzymes is lower in the Caco-2 cell line than in the small intestine. However, some enzymes have higher expression in this cell line than in intestine. This is the case, for example, of the SULT 1A2, 1A3, 1C1, or 2A1 [29,37–40].

Several studies have shown that phase II metabolism is more important in TC7 cell line than in Caco-2 cells, especially with respect to glucuronidation and sulfoconjugation levels [41] (Table 11.1). In these two cell lines, as in the enterocytes, the expression of phase II enzymes is in fact strongly linked to the differentiation state.

11.4.4 Drug Transporters

Drug transporters, belonging either to the solute carrier (SLC) family or to the ABC family, play a major role in drug absorption or secretion in the intestine. Indeed, the ABC pumps P-glycoprotein, multidrug resistance protein (MRP) 2 (ABCC2), and breast cancer resistance protein (BCRP, also known as ABCG2), located to the apical pole of enterocytes, are important in preventing the absorption of some chemicals into the systemic circulation, through expelling them in the lumen of the intestine. Other transporters located at the brush border pole of intestinal cells, such as the peptide transporter, PEPT1, or the organic anion transporters, OATP-A (SLCO1A2) and OATP-B (SLCO2B1), are by contrast involved in drug uptake into enterocytes. At the basolateral pole, organic solute transporters (OST α /OST β) and MRP3 (ABCC3) may facilitate the removal of the intracellular solutes into the basolateral side, thereby enhancing the absorption of drugs.

Most of the transporters found in human intestine are also detected in Caco-2 cells, including P-glycoprotein, BCRP, MRP2, PEPT1, OATP-B, and the monocarboxylate transporter (MCT)-1 (SLC16A1) [42]. The expression of transporters in Caco-2 cells such as OATP-B, BCRP, and MRP2 differ, however, more than fivefold than that found in the ileum, indicating that Caco-2 cells do not strictly reflect the pattern of transporter expression displayed by small intestine. In addition, it is noteworthy that the source of the Caco-2 cells, the culture conditions, and the culturing time are likely to affect

transport proteins; P-glycoprotein, MRP2, and PEPT1 mRNA levels have thus been shown to differ by at least a twofold factor in two independent Caco-2 cell clones [43]. Such differences may directly contribute to heterogeneity in transport activity between Caco-2 cells cultured in different laboratories [44].

With respect to transporter expression in TC7 cells, slightly higher mRNA levels of SLC transporters were found in these cells when compared to Caco-2 cells; these differences between the two cell lines were, however, considered as marginal [45].

Functional assays with Caco-2 cells, that is, permeability studies (see the following sections), may be performed with referent substrates for transporters: digoxin, vinblastine or paclitaxel (for P-glycoprotein), sulfobromophthalein (for MRPs and OATPs), methotrexate, estrone-3-sulfate, and pheophorbide A (for BCRP) and glycylsarcosine (for PEPT1). In addition, referent inhibitors of transporters may be used: verapamil or cyclosporin A (inhibiting P-glycoprotein), probenecid (inhibiting MRPs and OATPs), and fumitremorgin A (inhibiting BCRP). A recent paper from the International Transporter Consortium has proposed guidelines for investigating whether a compound may be a substrate for P-glycoprotein or BCRP using Caco-2 cells; an efflux ratio, basal to apical versus apical to basal, >2 , is in favor of a potential transport by P-glycoprotein or BCRP, which has to be confirmed by the use of transporter inhibitors [46]. Moreover, decision trees for P-glycoprotein and BCRP inhibitor interaction studies using bidirectional transport assays with Caco-2 cells are also provided in this chapter.

11.5 USING CELL MODELS

As Caco-2 cells are the most popular cellular model in studies on passage and transport, this and the following sections will only concern these cells.

11.5.1 Conditions of Culture

The complete morphological and functional differentiation of Caco-2 cells requires three weeks in culture under conditions described in Table 11.2. Many modifications of these conditions have been reported. Thus, the support of culture can be coated with, for example, type 1 collagen or matrigel, and the inactivated serum concentration decreased.

TABLE 11.2 Culture Conditions of Caco-2 Cells

	Caco-2 Cells
Culture medium	Dulbecco's modified Eagle's medium (classically)
Inactivated fetal calf serum (heat-inactivated at 56°C for 30 min)	Usually 20% (range, 5–20%)
glucose	25 mM (final concentration)
Nonessential amino acids	1%
Glutamine	2 mM (final concentration, range: 2–4 mM)
Cell density at seeding	$1 \times 10^5 - 4 \times 10^5$ cells/cm ²
pH	Usually 7.4
Medium change	Every 24–48 h

Figure 11.1 Schematic description of cells culture in nacelle system.

The enterocyte-like phenotype of Caco-2 cells is enhanced when cells are grown on semipermeable membrane (Fig. 11.1). In this case, Caco-2 cells can proliferate and differentiate in monolayer, reproducing the intestinal epithelium organization, where the apical compartment corresponds to the intestinal lumen and the basolateral compartment to the serous site. This method of culture allows the creation of an accessible apical and basolateral pole, with a possible asymmetry in the composition of culture medium. This asymmetry may allow, for example, studies of the passage of molecules from apical to basolateral side or from basolateral to apical side.

11.5.2 Essential Elements

The variation between laboratories can be associated to the heterogeneity of the Caco-2 cell line as well as to many factors influencing the morphological and functional characteristics of these cells. Among these factors, we can cite: the origin of cells, the culture conditions, the number of passage, the culture time, and the study conditions (concentration of drugs, materials used, temperature, methods of analysis, etc.) [6,47]. Thus, the transepithelial electrical resistance (TEER, a marker of the integrity of the cell monolayer) [48], or the expression of P-glycoprotein, [49–51] are influenced by cell differentiation level or by passage numbers of cells. Moreover, many studies show the influence of fetal calf concentration in the culture medium. Indeed, the serum provides hormones, growth factors, attachment factors, and other compounds necessary for growth and differentiation of Caco-2 cells. However, the exact composition of serum is often not fully characterized and varies from batch. This variation, for some authors, may favor the selection of a predominant clone over the course of passages, contributing to interlaboratory variability [52,53]. It is obvious that the removal of this variability is illusory. However, some rules can be observed to reduce it, such as to establish a master bank and a working bank to be sure to be in ranges of moderate numbers of passage, to try to always use the same serum; to strictly follow the protocols used for changing the culture medium or for reseeding cells, and to establish control of differentiation before the use of Caco-2 cells such as the analysis of the tight junction formation. These controls allow to reduce the variability of results and also to value the model.

11.5.3 Validation of Models

The use of Caco-2 model requires different controls [6,54] (Table 11.3). The first controls concerns the identification of the differentiated state of Caco-2 by measuring

TABLE 11.3 Example of Control and Methods of Control Used during Validation of the Caco-2 Cell Model^a

	Method Proposed for the Control	
Cell monolayer integrity	Measuring the TEER	TEER measurement can reveal toxicity or the tight junctions opening. TEER range of Caco-2 cells: 150–1600 ohm cm ²
	Measuring permeability of test compounds: • mannitol • PEG 400 • Lucifer yellow	These molecules do not usually spend the intestinal barrier
Cell differentiation	By measuring expression of differentiation markers: • sucrase isomaltase • dipeptidyl peptidase IV • alkaline phosphatase aminopeptidase	The expression of these markers is correlated with cell differentiation that depends on confluence of cells
Model validation (for passage studies)	By measuring the permeability of reference molecules	Proposed molecules with their apparent permeability (Papp): • Testosterone: 73×10^{-6} cm/s • Propranolol hydrochloride: 28×10^{-6} cm/s • Methothrexate: 1.2×10^{-6} cm/s The United States pharmacopeial (USP) convention proposes these molecules. If the Papp values obtained with Caco-2 cells are the same as the values given by USP ($\pm 20\%$), the model can be considered to be valid

Abbreviation: TEER, transepithelial electrical resistance.

^aRefs 6, 56, and 57.

the expression of differentiation markers such as sucrase-isomaltase (SI), dipeptidyl peptidase IV, alkaline phosphatase, or aminopeptidase. These enzymes are present at the brush border of enterocytes and some of them, such as SI, correspond to specific differentiation markers of the intestine. These checks can be performed on Caco-2 cells grown on plastic supports or on semipermeable membrane.

The second concerns the formation of cell layer and tight junctions (if cells are cultivated on semipermeable membrane). The integrity of the cell layer can be monitored by measuring TEER, which may be associated with the study of the passage of molecules such as lucifer yellow, an hydrophilic dye that does not pass the intestinal barrier.

Finally, the third control concerns the passage of the intestinal epithelium, represented by the monolayer of differentiated Caco-2 cells, by the study of passage of

reference molecules. The choice of reference molecules is difficult. The following compounds have been proposed by the US Pharmacopeia: testosterone, propranolol hydrochloride, and methotrexate; permeability values obtained should not be different $\pm 20\%$ of the proposed values [55].

If this part is related to the use of Caco-2 cells, it should be noted that most of the concepts described are also to be associated with the use of TC7 cells. However, keep in mind that TC7 cells possess some different characteristics, compared to Caco-2 cells, that is, a lower expression of P-glycoprotein (but remains higher than in the human small intestine); a doubling time shorter; a lower TEER than Caco-2 cells, and expression of CYP3A4. Thus, if controls and validation methods are the same for these two cell models, the experimental results obtained are not necessarily directly comparable.

11.6 EXAMPLE OF PROTOCOL: USING Caco-2 CELLS FOR PASSAGE STUDIES

This section provides a sample protocol for using Caco-2 cells in order to study the passage of various molecules through the cell monolayer formed by Caco-2 cells.

11.6.1 Cell Culture

The Caco-2 cells are used between passages 25 and 35. The culture medium (DMEM, 4.5 g glucose/L) is supplemented with 20% decomplexed fetal calf serum, 1% nonessential amino acids, 1% L-glutamine and antibiotics (100 μ g/mL penicillin and 100 mU/mL streptomycin). It is renewed every 48 h. The cells are seeded at 100,000 cells/cm² on a semipermeable membrane (Transwell, 0.4 μ m, COSTAR) and maintained in culture for 21 days after confluence. With these culture conditions, the cell confluence is usually obtained in four days.

11.6.2 Expression of Sucrase-Isomaltase (SI)

To determine whether our culture conditions lead to differentiated Caco-2 at the time of their use, we have studied expression of SI. The study of mRNA level of SI and β -actin was assessed by RT-PCR. The primers used for the study of mRNA of SI and β -actin of Caco-2 are: SI forward, 5'-gcccgcttccaagtgatta-3'; SI reverse, 5'-aaattgcagggtccaga-3'; β -actin forward, 5'-ggccatctcttgctc-3'; β -actin reverse, 5'-gccagagcaagagag-3'. The results show that, in our conditions of cell culture, enterocytic differentiation appears between the 5th and the 10th day of culture (Fig. 11.2).

11.6.3 Measurement of the TEER and Passage of Lucifer Yellow

Measurement of TEER of cell monolayer and the low passage of lucifer yellow, a dye not passing the epithelial barrier, are markers for the development of tight junctions. The TEER measure can be achieved through a volt-ohm meter (Evoma, World Precision Instruments Sarasota, FL). It is realized from the day after seeding (day 0) and after 3, 7, 14, and 22 days of culture. The intrinsic resistance of the semipermeable membrane

Figure 11.2 (a) Kinetic expression analysis, by RT-PCR, of sucrase-isomaltase (SI) and of β -actin in Caco-2 cells. (b) Measurement of TEER and the passage of lucifer yellow. These measurements were made from the day of seeding on semipermeable support (day 0) and after 3, 7, 14, and 22 day of culture. The results are expressed in Ohm- cm^2 for TEER and percentage of control (amount of cell-free passage) for lucifer yellow.

is subtracted from the total resistance (cell + membrane). After correcting the value obtained by the culture surface, the results are expressed in Ohm cm^2 ($\Omega \text{ cm}^2$). The permeation rate of lucifer yellow is determined by Papp calculation (see below). The sharp increase of TEER associated with the decrease in Papp of Lucifer yellow (Fig. 11.2) shows that our experimental conditions allow the formation of an impermeable cell monolayer.

11.6.4 Calculation of Apparent Permeability (Papp)

The current mode of implementation of the experience of passage is described in Fig. 11.3 [31]. There is a passage from the cell support (Fig. 11.1), which corresponds to the donor compartment or apical compartment in different acceptor compartments, or basolateral compartment, at regular time intervals. Using calculations as described in the Table 11.4, the curve representing the variations, in the acceptor compartment, of the quantity (Q) of interest molecule in function of time (T), can be built. The Papp were determined by linear regression of changes in concentrations in the acceptor compartment in function of time and by measuring the slope obtained (represented by dQ/dT , Table 11.4). The coefficient of apparent permeability (Papp) is expressed

Figure 11.3 A schematic representation of the method used for measurement of passage (donor compartment to acceptor compartment) of drug across monolayer of Caco-2 cells. C_0 , initial concentration; q , quantity of drug passing in acceptor compartment; t , interval time.

TABLE 11.4 Steps for Apparent Permeability (Papp) Determination

(1) Using disposition described in Figure 11.3, construction of the curve corresponding to the variations, in the acceptor compartment, of the quantity (Q) of interest molecule, in function of time (T).	Where $T_0 = 0$ and $Q_0 = 0$; $T_1 = t_1$ and $Q_1 = q_1$; $T_2 = t_1 + t_2$ and $Q_2 = q_1 + q_2$; $T_n = t_1 + t_2 + \dots + t_n$ and $Q_n = q_1 + q_2 + \dots + q_n$ (generally $t_1, t_2, \dots$ and t_n are identical)
(2) Determination of the slope dQ/dT by linear regression of the curve obtained in (1).	
(3) Calculate the coefficient of apparent permeability (Papp) by: Papp (cm/s) = $(dQ/dT) \times [1/(A \times C_0)]$	Where C_0 = initial concentration in donor compartment; A = surface-exposed (cm^2); dQ/dT = slope determined in (2).
(4) Construction of the curve corresponding to the slope (dQ/dT) in function of the initial concentration (C_0) in the donor compartment.	If the curve obtained is saturable, this indicates that the mode of passage probably involves a transport system. If the relationship between the slope (dQ/dT) and C_0 is linear, this indicates that the mode of passage is probably passive.

in centimeter per second. Measuring the slope (dQ/dT) as a function of the initial concentration (C_0) may be also used to determine if the passage uses a passive or active mode (Table 11.4).

The permeation rate of testosterone, propranolol hydrochloride, methotrexate, and the lucifer yellow are used as reference compounds. The US Pharmacopeia specifies the concentration tested ($C_0 = 0.3$ mM) and the Papp values to obtained (1.2×10^{-6} cm/s for methotrexate, 28×10^{-6} cm/s for propranolol, 73×10^{-6} cm/s for testosterone) [55].

Figure 11.4 shows the variations in quantity of different compounds in the acceptor compartment (basolateral) as a function of time. The results are expressed as a percentage of the initial amount at time zero in the donor compartment (apical). The slopes of linear regression curves obtained allow the calculation of various Papp (Fig. 11.4a). No significant difference was observed by comparing our values and those proposed by the US Pharmacopeia (Fig. 11.4b).

Figure 11.4 Passage study, across Caco-2 cell monolayer, of the reference molecules. (a) Evolution of methothrexate, propranolol hydrochloride, and testosterone concentrations in the acceptor compartment in function of time. Results are expressed as a percentage of the initial quantity (Q_0) in the donor compartment. (b) Comparison of apparent permeability (Papp) obtained with those proposed by the US Pharmacopeia. The results are expressed in 10^{-6} cm/s.

In summary, these results show that our culture conditions allow obtaining a fully differentiated cell monolayer.

11.7 CONCLUSION

Among the different models used to study the passage of the intestinal barrier and/or intestinal metabolism, the intestinal cell lines are the most used. Despite their faults, they are popular because of their ease of use, maneuverability, and ability to conduct studies that can last more than a few hours. However, the major problem that remains unresolved is the variability inter- and/or intralaboratory. In this section, some solutions are proposed, but they cannot solve the problem. Thus, the reference drugs proposed by the US Pharmacopeia are considered by some users as too rigid limits

and not accepted by all users. Another approach is the use of a collection of laboratory values, with internal specifications and criteria of acceptance for each assay system. The development of methods for isolation of enterocytes and goblet cells from human biopsies and culture techniques for maintaining these cells at an acceptable level of differentiation over several days is a goal that has likely to deserve further studies.

12.1 SUMMARY

Cytochrome P450 (CYP) enzymes expressed in liver microsomes are mainly involved in the biotransformation of drugs. CYP enzyme-related metabolic activity is a major determining factor in the pharmacokinetic profile, including bioavailability. A change in the metabolic activity derived from CYP inhibition and induction by comedication often results in adverse events or failure of drug therapy. The metabolic stability, CYP inhibition, and induction are key parameters in the optimization of lead structures and the selection of new molecular entities (NMEs) in drug discovery programs. Regarding these screenings, the advent of various evolutionary technologies has facilitated a paradigm shift from the traditional system to a robust moderate to high throughput system that meets the demands of modern drug discovery. Furthermore, the prediction of clearance of NMEs and alteration of the plasma concentration profiles

associated with drug–drug interactions (DDIs) caused by comedication has become an important task in pharmacokinetic studies. This chapter reviews advanced assay systems for metabolic stability, CYP inhibition, and induction, as well as predictive methods for pharmacokinetic profiles and DDI-associated changes in their profiles in humans.

12.2 INTRODUCTION

Pharmacokinetic profiles and DDIs such as drug-metabolizing enzyme inhibition and induction of NMEs in humans have increasingly become recognized as critical parameters of the developability of drugs [1]. Drug metabolism is a major factor governing pharmacokinetics. CYP enzymes are major drug-metabolizing enzymes and can catalyze the biotransformation of two thirds of commonly used drugs [2] and many other compounds such as steroid hormones, toxics, and carcinogens [3–5]. CYP enzymes consist of a superfamily of heme-thiolate proteins, and CYP enzymes responsible for drug metabolism are classified into three families, namely, CYP1, CYP2, and CYP3. The liver is the principal organ of drug metabolism and one or more of the various CYP enzymes expressed in the microsomal fraction are mainly involved in the metabolism. Shimada *et al.* [6] demonstrated that the most abundant CYP enzymes in the human liver are CYP3A subfamilies at 30% of the total spectrally determined CYP content, followed by the CYP2C subfamilies (20%), CYP1A2 (13%), CYP2E1 (7%), CYP2A6 (4%), CYP2D6 (<2%), and CYP2B6 (<1%). Accordingly, metabolic screening has been performed using human liver microsomes and fresh or cryopreserved human hepatocytes. Furthermore, those materials have been utilized to evaluate CYP inhibition, and hepatocytes in primary culture have been an indispensable tool for the assessment of CYP induction.

There is a growing awareness of the importance of predicting the pharmacokinetic profile in humans based on preclinical *in vitro* and/or *in vivo* data. The estimated human clearance (CL) allows predicting an effective dose by taking the efficacious plasma concentration into consideration, and the estimated plasma concentration profile, including maximum plasma concentration ($C_{\max}$) and half-life ($t_{1/2}$) in humans, are incorporated into the design of the dose regimen of the clinical study. Similarly, with regard to the inhibition and induction of CYP enzymes, the prediction of a change in CL by comedication provides an important position when selecting development candidates or creating a strategy for clinical DDI studies.

This chapter focuses on *in vitro* liver systems used to study metabolic stability, and CYP enzyme inhibition and induction both to optimize pharmacokinetics during early drug discovery and to characterize NMEs during late drug discovery or drug development. The predictive models to evaluate CL and/or plasma concentration profile are also reviewed, together with the evaluation of the influence of DDI on the pharmacokinetic profile in humans. Recently, it has been highlighted that first-pass metabolism in the small intestine has a great impact on bioavailability, and *in vitro* and *in vivo* studies have been directed toward the assessment of metabolism of CYP3A substrates in the small intestine [7]. However, this chapter focuses on such metabolic events in the human liver.

12.3 METABOLIC STABILITY

12.3.1 *In Vitro* System for Evaluating Metabolic Stability

In vitro systems of microsomes or hepatocytes are routinely used in drug metabolism studies to obtain an estimate of metabolic stability, usually expressed as intrinsic clearance (CL_{int}). In general, the CL_{int} can be estimated from the metabolite formation assay using the following equation:

$$CL_{int} = \frac{v}{S} = \frac{V_{max}}{K_m + S} \quad (12.1)$$

where S is the substrate concentration, v the metabolite formation rate, K_m the Michaelis constant, and V_{max} the maximum metabolite formation rate. In the drug discovery phase, identification of the main metabolites using *in vitro* or *in vivo* samples is difficult due to the labor-intensive and time-consuming processes. Hence, substrate depletion assay is widely used to estimate CL_{int} from the depletion or degradation rate constant (k_{dep}) of the substrate in microsome or hepatocyte incubation [8–10]. CL_{int} is estimated at a low substrate concentration such as 0.5–1 μ M [11–15], assuming that K_m values are at least higher than 5–10 μ M.

Drug metabolism is a major determinant factor to pharmacokinetics of NMEs. In prediction of the pharmacokinetic behavior, hepatic clearance (CL_H) can be estimated from the CL_{int} using physiological models: well-stirred model, parallel tube model, and dispersion model [16,17]. It is highly likely that the CL is calculated mainly based on the well-stirred model, simplified method among them, because the CL values estimated from the well-stirred model were reported to be within an acceptable range when compared with the other two models [16]. Assuming that drugs are cleared via hepatic metabolism from the body, the CL can be expressed by hepatic clearance (CL_H), which is calculated by the following equation based on the well-stirred model:

$$CL = CL_H = \frac{Q_H \times f_p \times CL_{int, in vitro}}{Q_H + f_p \times CL_{int, in vitro}} \quad (12.2)$$

where Q_H is hepatic blood flow, $CL_{int, in vitro}$ the intrinsic clearance (CL_{int}) scaled up to whole body using a scaling factor (microsomal recovery from the entire liver), and f_p the unbound fraction of protein binding in blood. The intrinsic clearance ($CL_{int}/f_{u,inc}$), which is corrected by unbound fraction ($f_{u,inc}$) of microsomal or hepatocyte incubation, is utilized on a case-by-case basis. Both unbound fractions are determined by equilibrium dialysis and ultracentrifugation [18]. An equilibrium dialysis method using 96-well apparatus has been developed for efficiently determining plasma protein binding [19].

Although knowledge of the binding parameters would be an essential part in precisely predicting CL, the metabolic stability has been a major indicator to guide the direction of lead optimization. Increased throughput of the metabolic screening has been achieved by developing an advanced robotic system in miniaturized format, such as 96-well plates [20–24]. Currently, Xu *et al.* [25] proposed a streamlined and intelligent workflow for metabolic stability that allows for high throughput analyses based on a novel postincubation pooling strategy coupled with ultraperformance liquid chromatography tandem mass spectrometry (UPLC/MS/MS). Establishment of a semiquantitative

relationship between CL_{int} and *in vivo* CL is a prerequisite for metabolic screening. However, some investigators pointed out a poor correlation between CL_{int} and CL in a relatively large data set, including various compounds [12,24,26]. Noticeably, Komura *et al.* [24] demonstrated that there was a certain relationship among derivatives with the same core structure, and even if a derivative showed a poor correlation, considering the f_p and/or $f_{u,inc}$ into the estimation of CL_{int} dramatically improved the relationship of $f_p \times CL_{int}$ versus CL or $f_p \times CL_{int}/f_{u,inc}$ versus CL. Moreover, Obach [27] and Riley *et al.* [28] demonstrated that the $CL_{int,in vitro}$ was correlated with *in vivo* intrinsic clearance ($CL_{int,in vivo}$) estimated from CL using physiological models incorporating both unbound fractions.

In the pharmacokinetic profiling for NMEs, linear pharmacokinetics would be qualitatively guaranteed on comparing the K_m value with the effective plasma concentration predicted in humans [8,29]. Obach and Reed-Hagen [8] applied the substrate depletion assay where the K_m value can be estimated from a concentration-dependent change in k_{dep} of unchanged compounds. For substrates metabolized possibly via a predominant pathway by one CYP enzyme, the estimated K_m values were comparable to those from metabolite formation assays using recombinant CYP enzyme. A similar result for K_m values was reported by Komura *et al.* [30]. Recently, a newly developed multiple depletion curve method has been reported to provide accurate estimates of K_m , in addition to CL_{int} [31].

Like liver microsomes, hepatocytes with integrated drug-metabolizing enzymes, including CYP enzymes, are an indispensable tool for metabolic studies. Cryopreserved human hepatocytes, which are preliminarily well characterized by metabolic activity of each CYP enzyme, are commercially available, and pooled or individual cryopreserved hepatocytes have been utilized. However, it is a question whether cryopreserved hepatocytes retain drug-metabolizing activities during storage. Griffin and Houston [32] comparatively evaluated CL_{int} for 20 biotransformations using fresh and cryopreserved rat hepatocytes. There was a tendency for both hepatocytes to provide a similar CL_{int} except for some highly cleared compounds that showed lower activity in cryopreserved hepatocytes. Additionally, comparable CL_{int} values in fresh and cryopreserved human hepatocytes were proven by Lau *et al.* [33] and Naritomi *et al.* [14].

In general, plasma protein binding, as well as metabolic stability, affect the *in vivo* pharmacokinetic behavior, and the dose-dependent CL of some drugs arises from concentration-dependent protein binding, particularly for drugs that are governed by drug metabolism [34,35]. A challenged approach, whereby test compounds were incubated with hepatocytes in the presence of serum, has been developed by Shibata *et al.* [13]. The approach, based on substrate depletion assay and termed the serum (or plasma) incubation method, provided CL_{int} values that included the influence of plasma protein binding, and the obtained value was regarded as the relevant parameter for predicting *in vivo* CL. Further investigation using the plasma incubation method with rat and human hepatocytes was performed to assess species differences in nonlinear pharmacokinetics of propafenone [10]. The nonlinear disposition in humans would be ascribed to the saturation of hepatic metabolism because of the low K_m values, which was in contrast to the linear pharmacokinetics in rats, which was associated with the offset of saturable metabolism by nonlinear plasma binding in rats. The plasma incubation approach was applied to investigate chiral-conversion-associated pharmacokinetics of ibuprofen in adjuvant-induced arthritis rats [36]. The developed substrate depletion

assay combined with plasma incubation can produce *in vivo* relevant parameter, including two different factors of metabolic stability and plasma protein binding, and must be a valuable tool in the drug discovery phase [17].

12.3.2 *In Vitro* System for Evaluating the Contribution of CYP Enzymes to Total Metabolism

The estimation of fraction (f_m) of drug metabolized by the target enzyme is required to precisely predict the effect of CYP inhibition and induction. Not only the identification of CYP enzyme involved in the major metabolic pathway of an NME but also the evaluation of contribution of the CYP enzyme to total metabolism has been conducted by investigating the effects of chemical inhibitors or an antibody against CYP enzymes on the metabolite formation rate in human liver microsomes after elucidation of the major metabolic pathways [37,38]. Further investigations have then been performed by comparing the metabolite formation rate with either recombinant human cytochrome P450 (rhCYP) enzymes or separate samples of human liver microsomes with a wide range of CYP activity [22,39]. The metabolic activity in each rhCYP enzyme needs to be extrapolated to the relevant data in human liver microsomes. Nakajima *et al.* [40] proposed the concept of relative activity factor (RAF) for the extrapolation by which ratios of marker activity specific to a certain CYP enzyme between rhCYP enzyme and human liver microsomes was used. The RAF method has been widely utilized to study the involvement of individual CYP enzyme in the formation of each metabolite [41–43].

There are practical difficulties involved in identifying the detailed chemical structures of the major metabolites during drug discovery and early drug development. The substrate depletion assays, which are a useful tool to estimate total metabolic intrinsic clearance [8,44], are also applied to evaluate the contributions of CYP enzymes to the metabolic elimination in human liver microsomes using chemical inhibitors specific to each CYP enzyme [9,45]. Furthermore, Emoto and Iwasaki [46] demonstrated the usefulness of a combination method of the RAF method and substrate depletion assay in early drug discovery.

Some of the drugs and NMEs are eliminated via multiple pathways, not only catalyzed by CYP enzymes but also conjugative enzymes. The usefulness of hepatocytes for evaluating the contribution of CYP enzymes in propafenone and propranolol metabolism, which are mediated by phase II conjugation alongside CYP2D6 [47], was demonstrated. The contribution of CYP2D6 to the metabolism of both drugs in human hepatocytes was consistent with corresponding *in vivo* data and was different from human liver microsomes that exhibited the overestimation of CYP2D6 involvement.

12.3.3 Prediction of *In Vivo* Pharmacokinetics in Humans

12.3.3.1 Physiological Approach (*In Vitro*–*In Vivo* Extrapolation). One of the major purposes of preclinical pharmacokinetic studies is to select NMEs and/or support a design of clinical studies including DDI, by the prediction of CL and plasma concentration profiles in humans [48]. The prediction of human CL is based on *in vitro*–*in vivo* extrapolation using the physiological models in which the $CL_{\text{int}, \text{in vitro}}$ obtained in *in vitro* systems is incorporated [16,49].

The first successful prediction of *in vivo* hepatic CL of YM796 from *in vitro* data with human liver microsomes and rhCYP enzymes was demonstrated by Iwatsubo *et al.* [50]. Moreover, a pronounced species difference in *in vivo* CL was kinetically explained by the K_m and V_{max} values in rat, dog, and human liver microsomes [51]. Retrospective prediction using marketed drugs and/or development candidates has been performed by some investigators. Obach *et al.* [52] evaluated the effect of plasma protein binding on CL prediction based on the well-stirred or parallel tube model. Impressively, not incorporating the f_p value in the physiological models yielded better predictability than taking the f_p value into consideration. On the other hand, investigation using a relatively large data set by Ito and Houston [53] demonstrated that a prediction model incorporating rather than ignoring the f_p value provided a better correlation between the predicted $CL_{int, in vitro}$ and the observed $CL_{int, in vivo}$. Furthermore, when both the f_p and $f_{u, inc}$ values were canceled out under the assumption that both binding parameters are equivalent, there was reportedly a poor relationship between the predicted $CL_{int, in vitro}$ and the observed $CL_{int, in vivo}$ values, particularly for acidic compounds [28]. This relied on the fact that the f_p values were lower than the $f_{u, inc}$ values, for acidic compounds unlike basic compounds.

The importance of nonspecific binding in *in vitro* system with microsomes and hepatocytes, on the CL prediction, was demonstrated by Riley *et al.* [28]. Compared with considering only plasma protein binding, incorporating both binding parameters in the well-stirred model produced a relatively better relationship regardless of the classification of acidic, neutral, and basic properties. Similar findings were reported in the prediction study of 29 drugs conducted by Obach [27], who concluded that the inclusion of both binding values gave the best agreement between the observed CL and the CL predicted from *in vitro* data. It should be noted that the unbound fractions in microsome and hepatocyte systems can be calculated using lipophilicity- or chemical structure-based *in silico* approaches [54–57].

It has been realized that there is a common issue of underestimation in various reported prediction studies. Some attempts have been made to clarify the underlying mechanism for the underestimation. Using benzodiazepine derivatives, which are subject to CYP-mediated elimination, kinetic profiles were compared between human liver microsomes and cryopreserved hepatocytes that possess the full spectrum of drug-metabolizing enzymes and transporters [58]. Although almost similar CL_{int} values were obtained with both evaluation systems, the retrospective analysis exhibited 5.6-fold underprediction in human hepatocytes as evidenced in liver microsomes.

A scaling factor has been regarded as a determining parameter of predictability. When scaling up the CL_{int} from microsome or hepatocyte studies to whole body basis, generally, a physiological scaling factor, which is obtained from average recovery of microsomal protein/number of cells per gram of liver multiplied by the average liver weight in humans, is utilized. However, the employed microsomal content and number of cells range widely from 29 to 77 mg protein/g liver and from 86 to 135×10^6 cells/g liver, respectively [59], and the most widely utilized values seem to be 45 mg protein/g liver and 120×10^6 cells/g liver, respectively. Ito and Houston [53] reported that the use of an empirical scaling factor, instead of the physiological scaling factor, dramatically improved predictability. In their analysis, the empirical factor was determined by regression analysis to obtain the best fit of $CL_{int, in vitro}$ and $CL_{int, in vivo}$ values for various drugs. Recently, Sohlenius-Sternebeck *et al.* [60] proposed a prediction method based on a regression line that adjusts for systematic underprediction. Namely,

the regression lines were drawn from the correlation between $CL_{\text{int}, \text{in vitro}}$ from rat liver microsome and hepatocyte studies and $CL_{\text{int}, \text{in vivo}}$ from intravenous studies with 52 drugs. The use of hepatocyte regression, in particular, yielded high predictability that CLs for 82% of the compounds were predicted within twofold error. An approach using the animal scaling factor was established by Naritomi *et al.* [61]. The animal scaling factor was determined by dividing $CL_{\text{int}, \text{in vivo}}$ by $CL_{\text{int}, \text{in vitro}}$ obtained from *in vitro* and *in vivo* studies of the individual compound in rats or dogs and was a drug-dependent intrinsic factor that possibly included unknown or unidentified mechanisms governing drug disposition. Correction of the scaling factor gave better prediction within twofold of the observed value. An impressive finding for the underprediction was reported by Huang *et al.* [62]. Their group highlighted that permeability and efflux status in P-glycoprotein (P-gp) and breast cancer resistance protein (BCRP)-expressing cells are a key factor affecting predictability of CL from CL_{int} and would be associated with the underprediction. For compounds that displayed high passive permeability and that are not good substrates toward the efflux transporters, the CLs would be predicted reasonably from the CL_{int} . In contrast, for compounds that showed either poor permeability or good substrates toward the transporters, the CL_{int} was unlikely to be predictive of CLs possibly due to a significant role of the transporters on their eliminations from the body.

It is increasingly realized that transporter-mediated liver uptake is involved in pharmacokinetic behavior with evidence that plasma concentrations of cerivastatin were increased with the inhibition of uptake transporter by the coadministration of cyclosporine A [63,64]. On the basis of the difference in concentration-dependent depletion profile between rat liver microsomes and hepatocytes, Parker and Houston [65] revealed that the liver uptake was a rate-limiting step for hepatic metabolism of saquinavir, nelfinavir, and ritonavir. A media loss assay was developed with rat hepatocytes to evaluate the impact of hepatic uptake on CL_{int} [66]. In contrast to the conventional assay in which the initial depletion rate constant is estimated from whole incubate (medium plus cells), the new concept was based on estimation of the disappearance rate constant only from the medium, which significantly improved predictability for a data set of 36 AstraZeneca compounds. Hence, the media loss assay can evaluate the hepatic active uptake process that confounded the CL prediction. Furthermore, the disposition of atorvastatin, cerivastatin, and indomethacin, known as substrates of uptake transporters, was investigated based on the measurement of cell and media concentration–time data in rat hepatocytes [67]. The developed physiological pharmacokinetic model that describes the ratio of the intracellular to extracellular concentration successfully predicted the effect of active uptake on the hepatic CL of atorvastatin and cerivastatin. Such a model would be a useful tool to predict *in vivo* CL of compounds that are subject to active liver uptake. In fact, using the *in vitro* kinetic data derived from human hepatocytes, analysis with a complicated physiologically based pharmacokinetic (PBPK) model incorporating a hepatic uptake process can successfully predict the *in vivo* pharmacokinetic profile of pravastatin, which is a typical substrate to solute organic anion-transporting peptide (OATP)1B1/1B3 [68].

12.3.3.2 Empirical Approach (Allometric Scaling). Alongside the *in vitro*–*in vivo* scaling described above, one of the best described techniques for predicting CL is allometric scaling, in which many physiological processes (blood flow, creatinine CL, heart rate, glomerular filtration, etc.) and organ size are defined by a power–law relationship

with the body weight of the species [69,70]. Owing to its simplicity, allometric scaling has been widely used to obtain human CL by extrapolating CL in animal species. Several methods have been developed; that is, simple allometry (SA), maximum life-span potential (MLP), brain weight (BrW), and rule of exponent (ROE) approaches associated with the choice of SA, MLP, or BrW based on the exponent of SA. Ward and Smith [71] developed a liver blood flow (LBF) method in which CL in humans is predicted based on the ratio of human and animal LBF rate. Monkey LBF method provided the best accuracy among the examined approaches, including allometric scaling [71,72]. Sinha *et al.* [73] reported that the ROE approach based on unbound oral clearance (unbound CL/F) gave the highest predictability among the examined allometric methods. Unbound fraction corrected intercept method (FCIM), by which both ratios of unbound fraction between rat and human plasma and a fixed power coefficient of 0.77 are considered, can be utilized for compounds that are not applicable to the ROE approach [73,74].

Interestingly, the concept that each property in the empirical and the physiological approach is integrated has been proposed by Lavé *et al.* [75,76]. The integrated approach was conducted using CLs in animal species that were normalized by a ratio of *in vitro* metabolic activities between hepatocytes of human and animal species and yielded 80% prediction within an error of twofold the observed CL.

Although the major disadvantage of allometric scaling is its empirical nature, this can, in some cases, be recognized as an advantage. Since it is different from *in vitro*–*in vivo* scaling, the application of allometric scaling does not need to clarify physiological mechanisms underlying elimination from the body and to understand species differences in the elimination mechanism [77]. In the early phase of drug development, characterizing other elimination mechanisms than the typical hepatic metabolism process, such as oxidation, is in many cases impossible. With regard to compounds that are eliminated from the body via unknown or multiple mechanisms, allometric scaling must be an indispensable predictor to human CLs.

12.3.3.3 Comparison of Empirical and Physiological Approaches. Comparative assessment between empirical and physiological approaches has been conducted by several investigators. Ito and Houston [53] demonstrated that the best method would be prediction from *in vitro* data using an empirical scaling factor. However, the use of a physiological scaling factor instead of the empirical scaling factor had similar accuracy as SA analysis. Obach *et al.* [52] evaluated the accuracy of human CLs predicted by an *in vitro* microsomal study without plasma protein binding (f_p) and by allometric scaling. The average error expressed by predicted/actual values was within a similar range (1.95 vs 1.91). Similar predictability between the empirical and the physiological approaches was also reported by Shiran *et al.* [78] and Tamaki *et al.* [79]. The latter group evaluated the comparative predictability of empirical and physiological approaches using data sets that were similarly characterized by a wide range of lipophilicity and CL. In contrast, using 16 marketed drugs, the ROE method was found to be more accurate than the *in vitro*–*in vivo* scaling method with *in vitro* microsomal data [80]. One issue of this kind of study is that each conclusion is derived from a different data set. To identify the best predictive method, predictability should be compared based on the same data set with a wide range of physicochemical properties.

12.4 CYP ENZYME INHIBITION

Comedication with two or more drugs is quite common in the treatment of diseases. One drug is often found to inhibit the drug-metabolizing enzymes of the second drug, mainly leading to an increased plasma concentration. As a consequence, such DDIs cause a risk particularly in patients given drugs with a narrow therapeutic index. In 1998, adverse drug reactions were reported as one of the most common causes of death of hospitalized patients in the United States, and most adverse effects involved drug metabolism [81]. Terfenadine [82], mibefradil [83], astemizole [84], cisapride [85], cerivastatin [86], and nefazodone have been withdrawn from the market due to toxicity or QT prolongation attributable to increased exposures by DDI [87]. Furthermore, DDIs have a huge impact on sales, as can be seen with cimetidine, a drug for the treatment of acid reflux, which lost sales because of DDIs that emerged in clinical and postmarketing approval studies of competing products [88]. To avoid costly failures of drug development, the assessment of DDIs has become an increasingly important task of the pharmacokinetic department.

The assessment of CYP inhibition is conducted both during the drug discovery and drug development phases. During drug discovery, the data of CYP inhibition are utilized to optimize the chemical structures and to identify NMEs with no or weak inhibitory activity by simplified moderate to high throughput methods. During drug development, detailed evaluation of CYP inhibition causes inhibitory kinetic data to both predict a change in plasma concentration profiles based on the mathematical models and to clarify the need for clinical DDI studies; for example, according to the FDA draft guidance [89] (<http://www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/ucm292362.pdf>), it was noted that CYP inhibition can be classified as either reversible or time-dependent inhibition (TDI) [90]. For reversible inhibition and TDI, our review focuses separately on assays that meet the requirements for the drug discovery and the development phases.

12.4.1 *In Vitro* Systems for Evaluating CYP Inhibition

12.4.1.1 Reversible Inhibition. Reversible inhibition involves rapid association and dissociation of drugs and enzymes and can be classified into competitive, noncompetitive, and uncompetitive modes based on the inhibitory mechanisms. The assay conditions of reversible inhibition have been described, together with the prediction criteria of the clinical relevance of competitive CYP inhibition, in the FDA's draft guidance and wave site [89]. Probe substrates and specific inhibitors of CYP enzymes are summarized in Table 12.1, together with time-dependent inhibitors. The guidance-defined method mainly using marketed drugs as practical probe substrates seems to be a gold standard for the assessment of CYP inhibition, in which the IC_{50} (inhibitor concentration causing a reduction of enzyme activity by 50%) or the K_i (inhibition constant) obtained from the dose response curve is estimated as a clinical relevant parameter to predict the possibility of a DDI in humans. However, the lead optimization process requires moderate to high throughput CYP inhibition screening to reduce the cost and shorten the time frame. The advantages and disadvantages of the various developed methods are shown in Table 12.2.

TABLE 12.1 Probe Substrates, Inhibitors, and/or Inducers in *In Vitro* CYP Inhibition or Induction Assessment

CYP Enzyme	Perspective of PhRMA (MBI) ^a		FDA Draft Guidance ^b		
	Substrate	Positive Control	Substrates	Inhibitors	Inducers
CYP1A2	Phenacetin Ethoxyresorufin	Furafylline	Caffeine Ethoxyresorufin Phenacetin ^c Tacrine Theophylline	Furafylline ^c α -Naphthoflavone	Lansoprazole Omeprazole
CYP2B6	Bupropion	Ticlopidine Thiotepa	Bupropion ^c Efavirenz ^c S-Mephenytoin Propofol	Clopidogrel Phencyclidine Ticlopidine Thiotepa Sertraline	Phenobarbital
CYP2C8	Paclitaxel Amodiaquine	Gemfibrozil-glucuronide Phenelzine	Amodiaquine Rosiglitazone Taxol ^c	Gemfibrozil Montelukast ^c Pioglitazone Quercetin ^c Rosiglitazone Trimethoprim	Rifampicin
CYP2C9	Diclofenac Tolbutamide S-Warfarin	Tienilic acid	Diclofenac ^c Flurbiprofen Phenytoin Tolbutamide ^c S-Warfarin ^c	Fluconazole Fluvoxamine Fluoxetine Sulfaphenazole ^c	Rifampicin

CYP2C19	S-Mephenytoin Omeprazole	Ticlopidine	Fluoxetine S-Mephenytoin ^c Omeprazole	Nootkatone Ticlopidine	Rifampicin
CYP2D6	Dextromethorphan Bufuralol	Paroxetine	Bufuralol ^c Debrisoquine Dextromethorphan ^c	Quinidine ^c	None identified
CYP3A4	Testosterone Midazolam	Mifepristone Verapamil Troleandomycin Erythromycin	Erythromycin Dextromethorphan Midazolam ^c Nifedipine Terfenadine Testosterone ^c Triazolam	Azamulin Ketoconazole ^c Itraconazole ^c Troleandomycin Verapamil	Rifampicin

^aGrimm *et al.* [91]; the list of substrates and inhibitors for time-dependent inhibition is based on perspective of Pharmaceutical Research and Manufacturers of America.

TABLE 12.2 Advantages and Disadvantages on Various Methods for Assessment of CYP Inhibition

Methods	Advantages	Disadvantages
Fluorescence	• Very high throughput	• Low selectivity and only use of recombinant CYP enzymes • K_i or IC_{50} that shows relatively low correlation with the corresponding data derived from marketed drugs
Radioactivity	• High throughput • Use of marketed drug with high selectivity as probe substrate • Use of recombinant CYP enzymes, liver microsomes, and hepatocytes	• Limited availability of probe substrates • High possibility of nonspecific binding when microsome concentration is high
LC/MS/MS	• Moderate–high throughput • Use of marketed drug with high selectivity as probe substrate • Use of recombinant CYP enzymes, liver microsomes, and hepatocytes • Inhibition on well-defined metabolic pathway • Cassette dosing (cocktailed approach) • Results applicable to new drug application (NDA)	• Ion suppression • High possibility of nonspecific binding when microsome concentration is high

Fluometric-based assays are regarded as a high throughput screening method by which substrates converted to fluorescent metabolites by CYP enzymes are utilized. Since the substrates exhibit low specificity toward each CYP enzyme, recombinant CYP enzymes but not human liver microsomes need to be used. Crespsi *et al.* [92] developed high throughput screening using 3-cyano-7-ethoxycoumarin as the substrate of CYP1A2, CYP2C9, CYP2C19, and CYP2D6 and resorufin benzyl ether as the substrate of CYP3A4. The obtained IC_{50} values showed high correlation to those of the traditional method using phenacetin, diclofenac, *S*-mephenytoin, bufuralol, and testosterone as the respective substrates. A similar microtiter plate assay with recombinant CYP enzymes and fluorescent probes was reported by Yamamoto *et al.* [93], who demonstrated comparable K_i values for nine CYP isoforms (CYP1A2, CYP2A6, CYP2B6, CYP2C8, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4) to the reported values of the conventional assay using human liver microsomes. Such a good relationship between the two assays was also reported by Bapiro *et al.* [94]. On the other hand, different results were found due to low sensitivity when VIVID®Red as the fluorescent substrate was utilized for CYP3A4 inhibition [95]. Furthermore, relatively lower IC_{50} values of CYP2C9, CYP2D6, and CYP3A4 in the fluometric assay than the conventional assay were found and were possibly associated with nonspecific binding

due to high microsome concentrations in the latter assay [96]. The reduction of microsomal concentration from 0.5 to 0.1 mg/mL led to an increase in the relationship. To increase the throughput, as well as to reduce the used amount of test compound, the fluometric assay was miniaturized to a 384-well plate format [97], and an integrated robotic system that consisted of liquid handlers, a plate hotel, and an incubator was applied to the fluometric assay [98].

Importantly, Kenworthy *et al.* [99] have recommended that multiple CYP3A4 probes, representing individual substrate groups, are used for *in vitro* assessment of CYP3A4-mediated DDI. Their group evaluated the inhibitory effects of 34 CYP3A4 substrates in the metabolism of 10 CYP3A4 probes in rhCYP3A4. As a consequence, erythromycin, cyclosporine, and testosterone were categorized as the large molecular group and dextromethorphan, diazepam, and benzodiazepine derivatives as the second group. Dihydropyridine derivatives such as felodipine and nifedipine showed a different inhibition profile from the other two groups. It was thus recommended that different CYP3A substrates (two or more substrates) chosen from each group are applied to the CYP3A inhibition assay. The sensitivity of various fluorescent substrates to CYP3A4 such as benzoxyresorufin (BzRes), 7-benzyloxy-4-trifluoromethylcoumarin (BFC), 7-benzyloxyquinoline (BQ), and dibenzylfluorescein (DBF) was comparatively evaluated by Stresser *et al.* [100]. BFC and BQ were the most and the least sensitive substrates, respectively, for evaluation of CYP3A4 inhibition. Additionally, IC₅₀ values from DBF correlated to those from testosterone 6 β -hydroxylation. Chauret *et al.* [101] also showed evidence for a similar correlation between DFB (3,4-difluorobenzyloxy)-5,5-dimethyl-4-(4-methylsulfonylphenyl)-furan-2-one and testosterone turnover. On the basis of the aspects of high sensitivity and/or clinical relevant substrate, BFC, DBF, and DFB are regarded to be suitable fluorescent CYP3A4 substrates for the high throughput assay.

Amelioration of conventional assay with marketed drug substrates was advanced with a short running time per sample analysis by developing the technologies of analytical equipment such as LC/MS/MS. Establishing simultaneous determination methods for metabolic activities of seven or nine CYP enzymes using LC/MS/MS allowed increasing the throughput in the assay [102,103]. Given that the use of two different CYP3A substrates was required, further development of simultaneous analysis, including two CYP3A activities (midazolam and dextromethorphan), was conducted by Li *et al.* [104]. Interestingly, as a cassette probe dosing/cocktail approach, a simultaneous incubation method using several probe substrates was developed [97,105–107]. In a validation study of the cocktail approach by Zientek *et al.* [97], the estimated IC₅₀ values of furafylline to CYP1A2, sulfaphenazole to CYP2C9, ticlopidine to CYP2C19, quinidine to CYP2D6, and ketoconazole to CYP3A4 were almost consistent between the cassette dosing and single dosing approaches.

In general, the IC₅₀ value is estimated based on the remaining CYP activity at multiple inhibitor concentrations such as 5–10 points. To increase the efficiency, various methodologies for the estimation of IC₅₀ have been developed. Moody *et al.* [108] developed two-point IC₅₀ determination in automated radiometric inhibition assay. The IC₅₀ estimated from 5 and 50 μ M inhibitor concentrations showed a good relationship with full IC₅₀ determination regardless of CYP enzymes. Moreover, a great challenge by Lin *et al.* [109] employed one-point IC₅₀ determination to maintain screening throughput instead of cassette incubation and pooled sample analysis. On the basis of the experiences of their group, there were high possibilities that the cassette dosing

generated additional interactions and that pooled sample analysis could potentially compromise MS/MS detection in case of strong inhibitors. The IC_{50} values calculated based on the one-point assay was in good agreement to those obtained by the eight-point assay, with slope of 0.95–1.02 for CYP enzyme activities. Additionally, Nakamura *et al.* [110] pointed out the possibility of ion suppression in LC/MS/MS analysis, which probably misleads the inhibitory effect of test compounds; that is, stable isotopes as internal standards of the quantification of metabolites of probe substrates are, in many cases, not commercially available. Use of [$^{13}C_4$ -, ^{15}N]-midazolam and 1'-hydroxymidazolam as the substrate and internal standard, respectively, successfully improved the effect of ion suppression.

Pharmacokinetics of some drugs involves various mechanisms such as uptake transporters, intracellular protein binding, and lysosomal uptake in addition to CYP-mediated metabolism. Hepatocytes are considered to retain those functions, and the usefulness of cryopreserved human hepatocytes in the assessment of DDI, alongside metabolic stability, was demonstrated by Li *et al.* [111]. *In vitro* DDI study for four hepatic uptake substrates, including atorvastatin and pitavastatin, was implemented using rat and human hepatocyte systems [112]. Those substrates were concentrated up to 1000-fold in the intracellular space of rat hepatocytes; however, only a fivefold difference in the IC_{50} values was pronounced. This was due to intracellular binding rather than extensive hepatic uptake. The importance of intracellular binding was also revealed by Brown *et al.* [113], who employed miconazole, fluconazole, ketoconazole, quinine, fluoxetine, and fluvoxamine with a high cell-to-medium ratio ranging from 4.2 to 6000. The cell-to-medium ratio was not correlated with the ratio of the K_i values between rat hepatocytes and liver microsomes; instead, there was a relationship between the unbound K_i values of the two assays. Accordingly, the high cell-to-medium ratio was not ascribed to hepatic uptake but to intracellular nonspecific binding. Intracellular accumulation associated with the binding must be considered as a key factor in *in vitro*–*in vivo* extrapolation. Importantly, McGinnity *et al.* [114] reported the usefulness of inhibition data of hepatocytes rather than recombinant CYP enzymes in the assessment of inhibition of quinidine and propafenone, CYP2D6 inhibitors. A significant difference in unbound IC_{50} ($IC_{50,u}$) toward the metabolism of bufuralol values between rhCYP2D6 and human hepatocytes was found with $IC_{50,u}$ of 0.02 versus 0.5 μM for quinidine and 0.02 versus 4.1 μM for propafenone, which was in contrast to similar $IC_{50,u}$ values for other examined CYP2D6 inhibitors.

As reported in the metabolic stability study, the plasma incubation method with human hepatocytes was applied to evaluate CYP inhibition by ketoconazole and fluconazole, a strong and a moderate CYP3A inhibitor, respectively [115–117]. On the basis of the concept that the examined inhibitor concentration in the plasma incubation is clinically relevant, *in vivo* inhibition potential was successfully derived from a relationship between the inhibitor concentrations and the remaining metabolic activity of the probe substrates in the plasma incubation, taking the f_m value into consideration. Moreover, the plasma incubation approach with human hepatocytes was applied to develop a single preincubation time method, which provided reliable prediction of DDI, regardless of CYP3A inhibitory mechanism [118].

For a drug that is biotransformed via multiple pathways mediated by CYP enzymes, in the general approach, the K_i value obtained in the individual metabolite formation need to be converted to the K_i value of whole metabolism by the weighted method with

the contribution fraction (f_m) of the inhibited CYP enzyme to CL for each pathway [114]. The substrate depletion assay has also been used to evaluate *in vitro* DDI [119] and can easily provide the K_i value of the inhibitor to whole metabolism. The estimated K_i values were similar to those of the metabolite formation assay in case of inhibition of omeprazole to diazepam metabolism. Hence, substrate depletion assay would enable to easily generate a K_i value for drugs that are eliminated via unidentified metabolic pathways.

12.4.1.2 Time-Dependent Inhibition. TDI, in general, results from irreversible covalent binding or quasi-irreversible noncovalent tight binding of a chemically reactive intermediate to enzymes that catalyze its formation. Grimm *et al.* [91] has distinguishably defined TDI and mechanism-based inactivation (MBI). TDI only indicates a kinetic definition and can be defined as a compound that time dependently increases an inhibitory effect during incubation with enzymes before the addition of substrates. MBI can be referred to as a *subset of TDI* demonstrating that enzymes act on the substrate to form a chemically reactive metabolite that subsequently inactivates the enzyme [120]. Accordingly, TDI, in some cases, includes reversible inhibition of the product (metabolite) formed during the incubation with enzymes. On the basis of the results of biochemical experiments, MBI can be classified into two groups: quasi-irreversible and irreversible inhibition.

Assessment of TDI has generally been performed by a shift in IC_{50} after preincubation with human liver microsomes or recombinant CYP enzymes in the presence of NADPH before incubation with CYP enzyme-selective probe substrates (Table 12.1). The shift in the IC_{50} value depending on the preincubation time cannot distinguish MBI and inhibition of the formed metabolite. In a general approach, after preincubation with human liver microsomes at high concentrations of 1–2 mg/mL, at least 10- or 20-fold dilution is necessary to quench further inhibition of probe substrate metabolism by the test compound or its metabolite. Use of a probe substrate concentration under saturation conditions ($>four\text{- or fivefold } K_m$) is recommended to minimize further inhibition of probe substrate metabolism by the test compound and its formed metabolite.

The rate of CYP enzyme inactivation is proportionally dependent on the inhibition concentration as described by the following equation [121]:

$$k_{obs} = \frac{k_{inact} \times [I]}{K_I + [I]} \quad (12.3)$$

where k_{obs} is the pseudo first-order rate constant of inhibition at the inactivator concentration $[I]$, k_{inact} the maximum inactivation rate, and K_I the inactivator concentration when the rate of inactivation reaches half that of k_{inact} . The k_{obs} can be determined from percentage remaining activity in multiple time- and concentration-dependent TDI assay. The logarithm of percentage remaining activity is plotted against the preincubation time for each concentration of test compounds, and the k_{obs} can be obtained by a slope from the linear regression analysis, and the k_{obs} and the inactivator concentration are fitted into Equation 12.3. Hence, to determine K_I and k_{inact} , five to six preincubation time points and multiple inactivator concentrations are required, and the TDI study is a time-consuming and labor-intensive work. Tables 12.1 and 12.3 indicate probe substrates and inactivators, and K_I and k_{inact} for CYP3A-mediated TDI using human liver microsomes, rhCYP3A4 or human hepatocytes, respectively.

Abbreviation: HLM, human liver microsomes.

As a simplified screening system for TDI with moderate to high throughput, IC_{50} shift assay using fluometric substrates (3-cyano-7-ethoxycoumarin for CYP1A2, CYP2C9, CYP2C19, and CYP2D6; BzRes and BFC for CYP3A4) has been developed [128]. In this assay, IC_{50} was continuously measured without terminating the enzyme reactions. Time-dependent reduction in IC_{50} values was found for quasi-irreversible inhibitors (isosafrole, erythromycin, troleandomycin, and diltiazem) and irreversible inhibitors (furafylline, propranolol, and mifepristone), which was in contrast to the constant IC_{50} for typical reversible inhibitors such as sulfaphenazole, tranilcypromine, quinidine, and ketoconazole. Similarly, Sekiguchi *et al.* [129] also conducted TDI assay of CYP3A4 using fluorescent substrate (BFC). In contrast, a disadvantage of

those fluometric assays is that metabolite inhibition and MBI cannot be distinguishably evaluated.

Single time- and concentration-dependent assay has been proposed as the first screening for TDI [121,125]. Watanabe *et al.* [121] reported automated single time- and concentration-dependent inhibition assay using midazolam as the CYP3A probe substrate, combined with a 10-fold dilution process of preincubation to avoid the effect of product inhibition. Using 171 marketed drugs, a diagram to evaluate the possibility of MBI-associated *in vivo* DDI was successfully described from the remaining activity of midazolam 1'-hydroxylation in the MBI assay and *in vivo* DDI information that included therapeutic blood or plasma concentration. Their group also developed a screening method to distinguish quasi-irreversible and irreversible inhibitors by the addition of ferricyanide into the preincubation solution. Noticeably, the assessment of MBI does not depend on the substrates (midazolam, nifedipine, and testosterone), while reversible inhibition requires the use of different types of substrates. A two-time point shift assay for TDI with a 5- or 10-fold dilution of preincubation solution was applied to the assessment of five major CYP enzymes (CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4) [123]. Moreover, to increase the throughput in the TDI assay, a cassette dosing approach was applied to the estimation of K_I and k_{inact} of prototypic inhibitors in cultured human hepatocytes [127].

A different strategy to evaluate TDI of CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4 was proposed by Lim *et al.* [130]. In their strategy, test compounds are first evaluated in apparent partition ratio (APR) screening, followed by detailed study with time- and concentration-dependent inhibition, and differentiation of quasi-irreversible inhibition and irreversible inactivation by oxidation of potassium ferricyanide and/or dialysis. APR was estimated by plotting percentage remaining activity as the function of the molar ratio of the test compound to CYP enzyme. Among 19 mechanism-based inhibitors and 4 quasi-irreversible inhibitors, the assay identified ritonavir, mibefradil, and azamulin as highly effective mechanism-based inhibitors of CYP3A, with an APR of 1.4–2.1, and isoniazid as a less effective inhibitor of CYP2C19 with an APR of 13,491. Such a widely dynamic range is regarded as an advantage in APR screening.

CYP3A5, along with CYP3A4, one of the major CYP enzymes, is expressed in adult human liver and small intestine [131], although the expression is genetically polymorphic [132]. The time-dependent inhibitors such as verapamil and its metabolites reportedly showed different inhibitory kinetics for CYP3A4 and CYP3A5 [133]. In addition, some of the compounds investigated by Soars *et al.* [126] did not show TDI to rhCYP3A5 but rhCYP3A4. Therefore, there is a possibility that a variable expression ratio of CYP3A4/3A5 in human liver microsomes contributes to interindividual variations in CYP3A-mediated DDI [134].

12.4.2 Prediction of *In Vivo* CYP Inhibition

12.4.2.1 Static Prediction Model. Assessment of the possibility of DDI and/or risk based on the predicted data has been included in the framework of pharmacokinetic studies. The prediction methods can be divided into two groups; namely, the static model describing the fraction of remaining CYP activity at a fixed inhibitor concentration and a PBPK model describing the time-dependent fraction of the remaining CYP activity associated with the plasma concentration–time curve of the inhibitor after administration.

In the static model, the most widely utilized method is the FDA-recommended approach based on $[I]/K_i$ ratio, in which $[I]$ indicates the mean steady-state $C_{\max}$ value for total drug (bound plus unbound) after administration of the highest proposed clinical dose [89]. An estimated $[I]/K_i$ ratio exceeding 0.1 is considered positive and follow-up *in vivo* assessment and/or detailed evaluation using mechanistic models are recommended.

The critical point of the static is which inhibitor concentration to use preferentially as the surrogate of the inhibitor concentration in the surroundings of the target enzymes in the liver because direct measurement of the inhibitor concentration is impossible. Some surrogate inhibitor concentrations have been investigated comparatively to evaluate the possibility of *in vivo* DDI. Komatsu *et al.* [135] challenged DDI prediction based on reversible inhibition between tolbutamide and various sulfonamides using K_i values estimated from an *in vitro* experiment in human liver microsomes. Irrespective of competitive or noncompetitive inhibition, the ratio of CL_{int} in the presence ($CL_{\text{int},+I}$) and absence of inhibitor ($CL_{\text{int},-I}$) can be described as the following equation when the substrate concentration is much lower than the K_m value:

$$CL_{\text{int},+I} = \frac{CL_{\text{int},-I}}{1 + \left(\frac{C_{\text{hep,inlet,u}}}{K_i} \right)} \quad (12.4)$$

where $C_{\text{hep,inlet,u}}$ is the unbound concentration of inhibitor. To avoid the false negative predictions, $C_{\text{hep,inlet,u}}$, which presents unbound maximum hepatic inlet concentration, was calculated as the sum of maximum unbound plasma concentration in the systemic vein ($C_{\max} \times f_p$) and the portal vein ($I_{\max} \times f_p$) from gastrointestinal absorption after oral administration, under the assumption that unbound inhibitor concentration in the liver equals that in the plasma. The blood concentration in the portal vein can be estimated as follows:

$$I_{\max} = \frac{D \times k_a \times F_a}{Q_h} \quad (12.5)$$

where k_a is the absorption rate constant, F_a the fraction of absorption, D the dose of administered inhibitor, and Q_h the hepatic blood flow. Approximately 4.8- and 1.8-fold increases in area under the plasma concentration curve (AUC) of tolbutamide, which were predicted by the coadministration of sulfaphenazole and sulfamethizole, were within a similar range as the reported *in vivo* data.

A comprehensive study on the prediction methods for reversible inhibition using Monte Carlo simulation [136] indicated that the use of maximum unbound hepatic inlet concentration did not provide false negative prediction, often accompanied with a produced overestimation, whereas an attempt using maximum unbound blood concentration in the systemic vein produced a false negative prediction. Furthermore, Ito and Houston [137] intensively investigated the effect of various estimates of inhibitor concentrations on the predictability of DDI based on the results of 193 DDI studies involving CYP2C9, CYP2D6, and CYP3A4. Excluding mechanism-based inhibitors, the use of total hepatic inlet concentration did not result in false negative prediction. This method may be a preferential approach in the selection of NMEs, which need to avoid false negative predictions, although the incidence of false positive predictions is controversial.

Importance of f_m and k_a values was highlighted by several investigators. The use of f_m values and the free hepatic inlet $C_{\max}$ successfully identified drugs that showed at least twofold increase in the AUC of the CYP-probe substrates, excluding known mechanism-based inhibitors from among 40 examined drugs [138]. In addition, Brown *et al.* [139] focused on the impact of f_m and k_a values on the prediction accuracy based on 115 clinical DDI studies involving CYP2C9, CYP2D6, and CYP3A4. The incorporation of f_m values into *in vivo* predictions using hepatic input plasma concentration resulted in 84% of studies within twofold of the *in vivo* data. In addition, the refined k_a value calculated from pharmacokinetic analysis reduced the number of overpredictions of CYP2D6 and CYP3A4. Ohno *et al.* [140] developed a robust and practical model, in which the time-averaged apparent inhibition ratio of CYP3A4 (IR_{CYP3A4}) calculated primarily based on AUC increases in DDI studies with 18 CYP3A inhibitors and midazolam was incorporated. The proposed method with f_m and IR_{CYP3A4} values is a versatile tool that enables the easy prediction of AUC increase by CYP3A4-mediated unknown interaction.

Regarding TDI, retrospective investigation by Ito *et al.* [141] focused on what inhibitor concentration was appropriate to predict midazolam and macrolide interaction. Application of maximum unbound hepatic inlet concentration gave a more accurate prediction, whereas underprediction tended to be observed in case of maximum unbound systemic concentration. Galetin *et al.* [142] evaluated 37 *in vivo* cases of irreversible inhibition of macrolides and diltiazem on the metabolism of CYP3A4 substrates, considering the inhibitory effect on the intestinal first-pass metabolism, using the following equation:

$$\frac{AUC_I}{AUC} = \frac{F'_G}{F_G} \times \frac{1}{\frac{f_{m,CYP3A4}}{1 + \sum_{i=1}^n \frac{k_{inact,i} \times I_{u,i}}{k_{deg,CYP3A4} \times (K_{I,u} + I_{u,i})}} + (1 - f_{m,CYP3A4})} \quad (12.6)$$

where $f_{m,CYP3A4}$ is the fraction of probe substrate metabolized by CYP3A4, $k_{deg,CYP3A4}$ is the *in vivo* degradation rate constant of CYP3A4 in the liver, I_u is either the average unbound systemic plasma concentration after repeated administration or the maximum unbound hepatic inlet concentration, and F'_G and F_G are the intestinal availability in the presence and absence of inhibitor, respectively. The use of unbound systemic plasma concentration of the inhibitor and f_m value resulted in 89% of studies predicted within twofold of the *in vivo* data.

The prediction accuracy of TDI is very sensitive to the CYP enzyme degradation rate. However, regarding CYP3A4 enzyme, the reported turnover ranged widely from 26 to 79 or 36 to 140 h, estimated from the *in vitro* and *in vivo* data, respectively [91]. Obach *et al.* [143] reported a prediction method for CYP3A-related MBI incorporating an *in vivo* CYP enzyme degradation rate constant estimated from clinical pharmacokinetic data, which was a similar model as to that by Galetin *et al.* [142], additionally with intestinal inhibitory kinetics. When using unbound systemic $C_{\max}$ as the *in vivo* inhibitor concentration, the most accurate predictions of DDI was obtained with a mean error of 1.64-fold. Additionally, using IC_{50} , IC_{50} fold-shift, K_I , and K_{inact} obtained in irreversible inhibition analysis, the relationship between each parameter was investigated. Surprisingly, fold-shift of IC_{50} before and after preincubation, which is often used as an indicator in the first screening, showed no correlation with K_{inact}/K_I , one of the indicators for potential irreversible inhibition. A good relationship was noted

between the shifted IC_{50} determined after 30-min preincubation and the K_{inact}/K_I or K_I value. Burt *et al.* [144] also reported that K_{inact}/K_I was correlated with $1/IC_{50}$ value after either a 10- and 30-min preincubation.

12.4.2.2 Physiologically Based Pharmacokinetic Model. In addition to K_i or K_I generally used as an index of hepatic enzyme inhibition, a key factor to the predictability is which inhibitor concentration is used. Those retrospective assessments using fixed inhibitor concentration would have given an important indication that the use of unbound hepatic inlet inhibitor concentration and unbound systemic inhibitor concentration appears to yield better prediction for reversible and irreversible inhibition, respectively. Not only to increase the predictability of DDI but also to describe the plasma concentration profile of substrates altered by a concomitantly given drug, the use of a plasma concentration–time curve of the inhibitor simulated from a PBPK model is essential instead of the fixed inhibitor concentrations.

With regard to reversible inhibition, estimation of *in vivo* relevant K_i value allowed quantitative prediction of CYP-mediated DDI [145]. The *in vivo* K_i values were determined by fitting the plasma concentration–time profiles of a substrate and an inhibitor to a simple PBPK model. Increased ratios of AUCs predicted using the *in vivo* K_i value estimated for each CYP inhibitor were in agreement with *in vivo* corresponding data and were more accurate relative to the prediction by the static model. Importantly, the discrepancy between *in vivo* K_i and *in vitro* K_i values was pronounced, possibly ascribed to nonspecific binding to liver microsomes that was well defined by lipophilicity.

For irreversible inhibition, prediction using a PBPK model has been challenged for DDI between 5-fluorouracil and sorivudine [146], triazolam and erythromycin [147], and midazolam and macrolides [141]. As already pointed out, CYP turnover rate ($k_{deg,CYP}$) is a key parameter that has an impact on the predictability. There has been difficulty to estimate the $k_{deg,CYP}$ of each CYP enzyme in the human liver in biological experiments, and hence, rat CYP data of 0.0005/ min was employed as human $k_{deg,CYP}$ in those studies.

DDI prediction has, in general, been performed under the following assumptions [141,147]: (i) substrate and inhibitor are orally administered according to the first-order rate constant and only undergo hepatic metabolism, (ii) unbound concentration in the hepatic vein and liver are equal due to a rapid equilibrium according to the well-stirred model, (iii) only unbound drug in the liver is subject to elimination, and (iv) disposition and metabolism of inhibitor are not altered by the inhibition of CYP3A4. In the prediction of triazolam and erythromycin interaction, when the K_I and k_{inact} values estimated in human liver microsomes or recombinant CYP3A4 were incorporated into a PBPK model, repeated administration of erythromycin at 333 mg three times a day for three days resulted in simulated reduction in hepatic CYP3A4 enzyme to 50–60% of the initial level [147]. Subsequently, the predicted 2.0- and 2.6-fold increase in triazolam AUC was derived from human liver microsomes and recombinant CYP3A4, respectively, which was similar to *in vivo* clinical data with a 2.1-fold increase. Similarly, for midazolam and macrolide interaction, simulation using the K_I and k_{inact} of macrolides estimated in human liver microsomes yielded a 2.9- to 3.0-fold increase in midazolam AUC after pretreatment with erythromycin, a 2.1- to 2.5-fold increase after pretreatment with clarithromycin, but little effect for azithromycin [141]. It should be noted that the

assessment of DDI in first-pass metabolism in the small intestine after oral administration is important to increase predictability, because the intestinal metabolism has reportedly had a great influence on the bioavailability of CYP3A4 substrates [7,145].

An advantage of the PBPK model beyond the static model in the DDI prediction is to estimate a change in the plasma concentration–time curves, including $C_{\max}$ and $t_{1/2}$, which would be associated with pharmacodynamics, in single and multiple ascending dose studies. Recently, advanced modeling and simulation tools combining *in vitro* data have increasingly been utilized to predict *in vivo* profile to optimize the dose regimen in a clinical trial to ensure that any interaction is appropriately measured. One such program is SIMCYP® (Simcyp Ltd., Sheffield, UK), which would give confidence to CL and DDI prediction [148,149].

12.5 CYP ENZYME INDUCTION

In vivo induction of CYP enzymes can result in significant clinical consequences with suboptimal pharmacological efficacy through the reduction in plasma concentration of comedicated drugs, and in the worst case, the increased formation of reactive metabolites. Clinical DDIs have been reported, with the therapeutic failures that comedication with CYP3A inducers lead to reduced ethinylestradiol levels from contraceptives, resulting in breakthrough pregnancies [150], and reduced cyclosporine level with organ rejection in transplant patients [151,152]. Induction activity on CYP enzymes has become one of the criteria for the selection of NMEs.

Studies on the induction have mainly been focused on CYP enzymes that are involved in the metabolism of a large number of drugs. CYP induction can occur as a result of either an increase in *de novo* synthesis of enzymes or a decrease in degradation associated with stabilization of the protein [153]. Regarding all CYP enzymes, excluding CYP2E1, which is subject to the stabilization [154], increased synthesis is common. Induction of CYP enzymes by drugs and other xenobiotics typically occurs via activation of receptors that regulate transcription. Induction of CYP1A1 and 1A2 is mediated through the aryl hydrocarbon receptor (AhR) [155]. CYP3A4 is induced through the pregnane X receptor (PXR), which is also involved in the induction of CYP2C9 and organic anion transporters [156]. Therefore, it is considered that CYP2C9 induction consistently tracks with the expression level of CYP3A4. PXR is reported to have a synergistic effect with the glucocorticoid receptor (GR), although the mechanism is not fully understood [157]. The constitutive androstane receptor (CAR) is a member of the gene superfamily of nuclear hormone receptors and a key transcription factor in hepatic CYP induction [158,159]. PXR and CAR are demonstrated to be responsible for coordinating the regulation of a large number of drug-metabolizing enzymes, including CYP isoforms (CYP2B6, CYP2C9, and CYP3A4) and transporter genes [160,161].

Since almost all *in vivo* hepatic events, including drug metabolism and induction, can be evaluated by the hepatocyte system, human hepatocytes in primary culture are currently utilized in the assessment of enzyme induction as the gold standard in preclinical DDI studies. However, due to the limited availability of high quality human hepatocytes and interindividual variability in response to inducers, alternative assay systems with at least moderate throughput have been developed for the lead optimization under pressure from project organizations: reporter gene assay for PXR and AhR, and other cell lines such as nontumorigenic immortalized human hepatocyte line, Fa2N-4 cells, and a new human hepatoma cell line, HepaRG. The current status

TABLE 12.4 Advantages and Disadvantages on Various Methods for Assessment of CYP Induction

Methods	Advantages	Disadvantages
Reporter gene assay	• Very high throughput • Cost effective	• No consideration of metabolic elimination of inducer • Poor correlation of $E_{\max}$ with hepatocyte • Assessment of transcription activation only
Hepatocyte	• Gold standard method • Possible existence of functions regarding induction mechanism, nuclear transporters, uptake transporter, efflux transporter, and drug metabolism • Determination of both mRNA and activity level • Results applicable to NDA • Evaluation of all process involved in induction	• Low throughput • High cost and labor intensive • Limited availability of high quality fresh hepatocytes • High interindividual variation
HepaRG	• Moderate throughput • Determination of mRNA and activity level • High expression of nuclear factors and transporters • A certain level of drug-metabolizing activities • EC_{50} and/or $E_{\max}$ correlated with hepatocytes	• Alternation of drug-metabolizing activities by culture condition with DMSO • A relatively large lot-to-lot variation in fold induction reported
Fa2N-4	• Moderate throughput • Similar response over the passage • EC_{50} correlated with hepatocytes	• Extremely low expression of CAR • Low drug-metabolizing activities • Low expression of hepatic uptake transporters

of CYP induction assay and its prediction is separately reviewed. The advantages and disadvantages of those assay methods and the *in vitro* inducers recommended by the FDA draft guidance are listed in Tables 12.1 and 12.4, respectively. In addition, *in vitro* parameters for CYP induction are summarized in Table 12.5.

12.5.1 In Vitro System for Evaluating CYP Enzyme Induction

12.5.1.1 Reporter Gene Assay. PXR was first identified as an orphan nuclear receptor responsive to pregnanes by Kliewer *et al.* [169], who found that PXR induces the CYP3A family. Furthermore, their group [170] demonstrated a differential activation profile in human pregnane X receptor (hPXR) and mouse pregnane X receptor (mPXR)

in the reporter gene assay. That is, hPXR was activated by clotrimazole, rifampicin, and dexamethasone-*t*-butylacetate, which was in contrast to low activation of mPXR by clotrimazole and rifampicin together with high activation by pregnenolone 16 α -carbonitrile (PCN).

The reporter gene assay for PXR has been used as a convenient high throughput tool to identify compounds with the potential to induce CYP3A4. Successful results to classify inducers and noninducers based on PXR reporter gene assay were reported by Persson *et al.* [171]. Seven *in vivo* inducers, one weak *in vivo* inducer, and noninducers were evaluated by the luciferase reporter gene assay for PXR with xenobiotic responsive enhancer module (−7836/−7208) and the −362/+53 proximal promoter from CYP3A4 in the pGL3 basic vector. When unbound *in vivo* AUC was taken into consideration, the assay identified inducers and noninducers separately. For phenobarbital, phenytoin, and troglitazone, which are prototypic inducers, $E_{\max}$ value, expressed as percentage of maximum rifampicin induction, was 71.7%, 20.6%, and 45.0%, respectively; however, lovastatin showed no response in the assay. Similar results for the rank order of induction responses (rifampicin > phenobarbital > phenytoin) in PXR activation assay was reported by Luo *et al.* [172].

Since hPXR and human glucocorticoid receptor (hGR) would reportedly contribute to the transcriptional regulation of CYP3A4 gene by a large number of xenobiotics [173], *in vitro* reporter gene assay, in which plasmid of hPXR and hGR was transfected into human hepatocyte carcinoma cell line, HepG2 cells, was developed [163]. This system utilized CYP3A4 proximal promoter (−1087 to −57) linked to a secretory alkaline phosphatase (SEAP) reporter gene. To increase the efficiency of estimating EC_{50} (concentration at half the maximum induction ratio) values in the assay, it was attempted to decrease to four- from eight-point concentrations on the dose–response curve. The four-point assay with respect to well-known CYP3A4 inducers produced a similar dose–response curve to the eight-point assay, and the highest fold induction based on $E_{\max}$ in lovastatin, followed by simvastatin $\approx$ troglitazone > rifampicin > phenobarbital > phenytoin.

To evaluate CYP1A1 induction, a cell-based high throughput screening system is also available. Yueh *et al.* [174] and Chao *et al.* [175] established stable cell lines harboring a luciferase reporter gene integrated in artificial multiple xenobiotic response elements. Moreover, the reporter gene assay was developed using HepG2 cells stably transfected pTX.DIR and pSV₂-Neo [171]. On the basis of the luciferase activity associated with AhR activation, the EC_{50} value of lansoprazole, omeprazole, and indole-3-carbinol was estimated to be 5.9, 18.1, and 55.8 μ M, respectively, whereas activation was not pronounced for phenytoin, primaquine, rifampicin, and troglitazone. Noticeably, the liver slice system with the treatment of primaquine, however, produced 17-fold induction of CYP1A1 mRNA, and phenytoin, rifampicin, and troglitazone appeared to show the induction of CYP1A1 mRNA, although to a lesser extent.

The molecular mechanism of AhR-mediated activation has been extensively studied for CYP1A1; however, the mechanism for CYP1A2 remains unclear. Recently, Sato *et al.* [176] have set up a dual reporter gene assay that enables simultaneous and rapid determination of transcriptional activation of CYP1A1 and 1A2 genes using indicators of luciferase and SEAP activity, respectively. Given that transcriptional activation of CYP1A1 and 1A2 genes is reportedly regulated simultaneously through a common regulatory element existing between the genes that act bidirectionally [177], the stable cell lines contain 23-kb intergenic spacer regions alongside the reporter gene. The

reporter gene assay detected the induction of CYP1A2 by omeprazole, lansoprazole, and alendazole, although the extent of induction of CYP1A2 was lower than that of CYP1A1. Therefore, the assay with the stable cell line may be a useful assessment tool for induction of CYP1A2 in addition to CYP1A1.

On the basis of the survey of Pharmaceutical Research Manufactures of America (PhRMA) to its member companies [178], PXR reporter gene assay is used by a majority of PhRMA companies surveyed, but only 23% of the companies assesses CYP1A induction potential of compounds in the AhR reporter gene assay.

12.5.1.2 Human Hepatocytes. Human hepatocytes have molecular mechanisms underlying CYP induction from signal transductions via nuclear receptors, in addition to drug-metabolizing enzymes and transporters involved in liver uptake and efflux, and those features are a benefit over other assessment systems. Accordingly, human hepatocytes have been regarded as a reliable *in vitro* system and the gold standard for evaluating enzyme induction of NMEs [179,180].

FDA draft guidance for DDI studies has recommended the evaluation of CYP induction, before clinical study, by a change in CYP enzyme activities (and CYP mRNA) in the primary culture of hepatocytes treated with test compounds and positive controls [89]. Fresh and cryopreserved human hepatocytes are commercially available. Comparative assessment of induction response between both hepatocytes demonstrated that there is not a significant difference in fold induction of CYP1A2 and CYP3A4 by lansoprazole and rifampicin, respectively [181]. The fresh hepatocytes exhibited higher activities of CYP1A2 and CYP3A4 enzymes than the cryopreserved hepatocytes; however, the use of fresh hepatocytes in a timely manner is difficult. Furthermore, there is large interindividual variability in response to inducers in fresh hepatocytes as demonstrated by Kostrubsky *et al.* [179].

Large interindividual variation in the basal activities of testosterone 6 β -hydroxylation and ethoxyresorfin deethylation was reported by some investigators [179,182,183]. Interestingly, Kostrubsky *et al.* [179] made it clear that there was an inverse relationship between fold induction and basal CYP3A4 activity when either taxol or rifampicin was exposed in hepatocytes; that is, hepatocytes with a low basal CYP3A4 activity tended to provide a large extent of induction and vice versa. As a consequence, the variation was decreased for the level of CYP3A4 activity enhanced after the treatment of the inducer, being possibly associated with a feedback regulation. A small lot-to-lot difference in the induced CYP3A4 activity was suggested by Chang *et al.* [184]. Moreover, a weak relationship was pronounced for the $E_{\max}$ values between different lots of hepatocytes, but the EC_{50} values were well correlated [162]. To dissolve these issues in the fresh hepatocytes, cryopreserved hepatocytes precharacterized as high quality lot in terms of induction and drug-metabolizing activities would be preferentially applicable to the CYP induction study.

A comprehensive work using a large number of human hepatocyte lots (62 lots) was conducted by Madan *et al.* [182], who evaluated the extent of induction of individual CYP activity after incubation with either β -naphthoflavone, phenobarbital, or rifampicin. The highest extent of induction in the treatment of rifampicin was noted for CYP2C19 activity (37-fold, $n = 10$), followed by CYP2B6 activity (13-fold, $n = 14$), CYP3A4 activity (10-fold, $n = 61$), CYP2C8 activity (5.2-fold, $n = 4$), CYP2C9 activity (3.5-fold, $n = 10$), and CYP2E1 activity (2.2-fold, $n = 5$). CYP1A2 activity was induced by 13-fold after treatment of β -naphthoflavone ($n = 28$).

Ritonavir is not only an inducer but also an irreversible inhibitor of CYP3A4, and the induction activity of ritonavir was evaluated in both the PXR reporter gene assay and the hepatocyte assay [172]. Unlike mRNA level, testosterone 6 β -hydroxylation activity in hepatocytes was reduced below the basal level after the treatment of ritonavir, whereas ritonavir displayed a strong induction in the PXR reporter gene assay. Similar dual activities as CYP inducer and inhibitor were also reported for troleandomycin. Induction parameters derived from the PXR reporter gene and human hepatocyte assay were comparatively evaluated using 24 compounds, including 14 time-dependent inhibitors [162]. The EC₅₀ values of CYP3A4 mRNA in hepatocytes were correlated with those in the PXR reporter gene assay. On the contrary, the $E_{\max}$ values of midazolam 1'-hydroxylation activity in hepatocytes showed poor correlation with the corresponding data for mRNA, which was attributed to metabolic activity reduced by TDI in hepatocytes. As expected, the exclusion of time-dependent inhibitors from the compounds examined led to dramatic improvement of the relationship. Fahmi *et al.* [185] comparatively investigated usefulness of CYP3A activity and mRNA as the reliable marker in the assessment of CYP3A induction. It was pointed out that cutoff value based on fold increase in CYP3A mRNA is the best classification on induction potential relative to that in CYP3A activity. This suggests that the measurement of CYP mRNAs, in addition to CYP activities, is important to characterize the induction profile of compounds when detailed information on TDI is not available. Interestingly, quantitative protein determination method for CYP induction by LC/MS/MS was reported [186]. A high throughput LC/MS/MS approach quantified CYP protein itself by measuring the isoform-specific peptides released by enzymatic digestion of hepatocyte incubation, with high reproducibility. This approach detected small fold change in CYP isoforms, and the induction of CYP3A5 by phenobarbital in human hepatocytes was detectable. The protein determination may be an alternative approach in the assessment of CYP induction.

CYP induction study using hepatocytes is a labor-intensive and time-consuming process. The use of a cassette dosing approach in the measurement of CYP enzyme activity would lead to a decrease in the workload of the induction study. Mohutsky *et al.* [187] employed cocktail probe substrates that were composed of phenacetin (CYP1A2), diclofenac (CYP2C), and midazolam (CYP3A4) to evaluate alternation of CYP enzyme activities. The extent of induction of CYP activities was comparable between the single and cassette dosing approaches regardless of CYP inducer or hepatocyte lot. In current study on profiling CYP induction of statins in human hepatocytes, Feidt *et al.* [188] demonstrated applicability of cocktail assay with metabolic activities of seven CYP enzymes: CYP1A2 (phenacetin), CYP2B6 (bupropion), CYP2C8 (amodiaquine), CYP2C9 (tolbutamide), CYP2C19 (*S*-mephenytoin), CYP2D6 (propafenone), and CYP3A4 (atorvastatin).

12.5.1.3 HepaRG Cells. A human hepatoma cell line, HepaRG, derived from a hepatoma cellular carcinoma has been utilized to evaluate CYP induction activity. In differentiated HepaRG cells after seeded at low density, mRNA levels of CYP3A4 and activity of testosterone 6 β -hydroxylation were low in the absence of 2% dimethyl sulfoxide (DMSO), compared with the corresponding data in the presence of 2% DMSO [189]. The low activity in the absence of DMSO was remarkably induced by rifampicin treatment. Profiling of the mRNA and activity level of drug-metabolizing enzymes in

differentiated HepaRG cells was conducted by Kanebratt and Andersson [190]. The differentiated HepaRG cells at one day after removal of DMSO from the medium showed comparable mRNA levels to human hepatocytes. Relative to human hepatocytes, the metabolic activities toward midazolam, naloxone, and clozapine in HepaRG cells were similar, whereas the HepaRG cells exhibited lower activity for 7-ethoxycoumarin and dextromethorphan associated with low levels of CYP2E1 and CYP2D6. Various nuclear receptors such as AhR, CAR, and PXR were retained at a high level, regardless of the presence or absence of DMSO [189]. HepaRG cells that exhibited the expression of nuclear receptors alongside most of all drug-metabolizing activities would be suitable for CYP induction screening, although the activity levels may depend on the culture condition.

Evaluation of EC_{50} needs a widely ranged dose–response curve. To avoid problems with cellular toxicity and solubility in the higher inducer concentration range, a new score to evaluate induction activity at lower concentrations was introduced. The score was defined as an F_2 value, which was obtained from the concentration at a twofold increase from baseline for mRNA and enzyme activity levels, instead of EC_{50} values [191]. The obtained F_2 values were correlated with decreases in AUC of CYP3A4 probe substrate drugs after treatment with inducer.

Lot-to-lot variability in CYP3A induction assays was reported in HepaRG cells [165]. The coefficients of variation (CV%) of the E_{max} of rifampicin, phenobarbital, and carbamazepine were 61.0%, 138.4%, and 198.8% and of the EC_{50} were 95.8%, 88.6%, and 198.3%, respectively, in four different lots of HepaRG. Since the variation tended to be smaller at lower rather than higher concentrations in the dose–response curve, the use of rifampicin- or phenobarbital-normalized fold induction at lower concentrations successfully minimized the variation.

12.5.1.4 Fa2N-4 Cells. Fa2N-4 cells are nontumorigenic and originated from human hepatocytes immortalized by transfection with the SV40 large T-antigen [192]. Hariparsad *et al.* [168] extensively characterized basal mRNA expression profiles with respect to 64 drug disposition genes that included drug-metabolizing enzymes, nuclear receptors, and transporters in Fa2N-4 cells, compared with four batches of human hepatocytes. Fa2N-4 cells showed a higher expression in almost all transcription factors and coactivators/corepressors associated with PXR-mediated enzyme induction. CYP3A4 expression level in hepatocytes was variable between the lots and ranged from 0.3- to 18-fold of Fa2N-4 cells. It was pointed out that midazolam 1'-hydroxylation activity in Fa2N-4 cells was ~100-fold lower than that in hepatocytes [167]. Compared with hepatocytes, the expression level of PXR, AhR, and GR was higher in Fa2N-4 cells, but significantly, the expression level of CAR was two orders of magnitude lower in Fa2N-4 cells [168]. Fa2N-4 cells also tended to show a significantly lower basal expression of several major hepatic uptake transporters, including sodium/bile acid cotransporter 10A1 (NTCP), solute carrier organic cation transporter 22A1 (OCT1), OATP1B1, and OATP1B3. In particular, the expression level of OATP1B1/1B3 in Fa2N-4 cells was 50-fold lower than that in hepatocytes, indicating that there is high possibility that substrates of those transporters apparently show low induction potency in Fa2N-4 cells because of low intracellular concentrations. This has been evidenced by the relatively higher EC_{50} values of rifampicin, which is substrate to OATP1B1/3, in Fa2N-4 cells (1.9–8 μ M) than hepatocytes (0.1–2.6 μ M), as shown in Table 12.5.

Rifampicin was regarded as an outlier in the obtained good relationship when EC_{50} values for various CYP3A inducers were plotted between Fa2N-4 cells and hepatocytes [162]. Noticeably, 6-(4-chlorophenyl)imidazo[2,1-*b*][1,3]thiazole-5-carbaldehyde *O*-(3,4-dichlorobenzyl)oxime, a CYP2B6 inducer, produced no induction in Fa2N-4 cells, which was in contrast to hepatocyte data with E_{max} of 6.8-fold. This difference was consistent to extremely low expression of CAR in Fa2N-4 cells.

The usefulness of Fa2N-4 cells to identify CYP3A4 inducer was evaluated using 24 compounds selected from induction profiles in human hepatocytes [166]. Fa2N-4 cells showed CYP3A4 induction exceeding twofold for all 18 positive controls and less than 1.5-fold for all 6 negative controls. In addition to CYP3A4, induction of CYP1A2 and CYP2C9 was evaluated in Fa2N-4 cells [193]. Treatment of β -naphthoflavone, rifampicin, or phenobarbital yielded similar fold induction to CYP1A2, CYP2C9, and CYP3A4 mRNA levels, relative to human hepatocytes. Furthermore, a cassette dosing approach with tacrine for CYP1A2, diclofenac for CYP2C9, *S*-mephenytoin for CYP2C19, and midazolam for CYP3A4 was employed to assess induction based on changes in CYP activities in Fa2N-4 cells [194]. A comparable dose–response curve was obtained in both the cassette dosing and single dosing approaches. Similarly, successful measurement of induction activities in the cassette dosing approach was conducted by Kenny *et al.* [167].

12.5.2 Prediction of *In Vivo* CYP Induction

The first investigation of quantitatively predicting effects of CYP1A and CYP3A induction on *in vivo* exposure of substrates to those CYP enzymes was conducted by Kato *et al.* [195], who used *in vitro* and *in vivo* data of various inducers such as rifampicin, carbamazepine, phenytoin, dexamethasone, phenobarbital, and omeprazole. *In vitro* EC_{50} and E_{max} values were calculated from an E_{max} model using an averaged unbound concentration of inducers in the incubation medium with hepatocytes. The magnitude of AUC increase in comedicated CYP1A2 or CYP3A substrates was predicted based on the difference in CL_{int} values before and after treatment of inducers using the E_{max} model in which unbound steady-state plasma concentration of inducers after repeated administration was incorporated. With respect to CYP3A, predicted and observed induction ratios were correlated, whereas the prediction of CYP1A induction by omeprazole was overestimated. This discrepancy in CYP1A induction would be partly because of the underestimation of omeprazole exposure in the incubation medium with hepatocytes.

Ohno *et al.* [196] constructed a robust and accurate prediction method based on the equation of $1/(1 + CR_{CYP3A4} \times IC_{CYP3A4})$, in which CR_{CYP3A4} is the ratio of the apparent contribution of CYP3A4 to oral CL of a substrate (i.e., f_m) and IC_{CYP3A4} represents the apparent increase in CL of substrate by coadministration of prototypical inducers to CYP3A4. IC_{CYP3A4} was calculated for seven inducers based on a reduction in AUC of coadministered simvastatin, a standard substrate of CYP3A4. Rifampicin was found to be the most potent inducer among the tested compounds, with an IC_{CYP3A4} of 7.7, followed by phenytoin (4.7) and carbamazepine (3.0).

Relative induction ratio (RIS) was proposed as an indicator to predict percentage decrease in AUC of CYP3A4 substrate by comedication of CYP3A4 inducers [166]. RIS can be estimated from *in vitro* induction data (E_{max} and EC_{50} values) in Fa2N-4 cells and human hepatocytes with efficacious free plasma concentration using the

following equation:

$$\text{RIS} = \frac{E_{\max} \times C_{\text{eff,free}}}{\text{EC}_{50} + C_{\text{eff,free}}} \quad (12.7)$$

where $C_{\text{eff,free}}$ is the unbound plasma concentration of inducers after a standard therapeutic dose. In case of CYP3A4 inducers (rifampicin, phenobarbital, carbamazepine, troglitazone, etc.), the RIS score estimated from *in vitro* parameters in Fa2N-4 and human hepatocytes was in good agreement with the decrease in AUC of coadministered CYP3A4 substrates such as midazolam or ethinylestradiol.

The dose–response curve using widely ranged inducer concentrations can be described using *in vitro* parameters such as $E_{\max}$ and EC_{50} . In some cases, those parameters cannot be estimated as a result of cellular toxicity or a solubility problem in the high concentration of inducers. As an alternative indicator, Kanebratt and Andersson [191] have proposed to use F_2 parameter, which is an inducer concentration giving twofold induction of CYP3A4 mRNA from baseline. Relationship between the AUC/F_2 (ratio of *in vivo* AUC of inducer to F_2) and percentage decrease in *in vivo* AUC of CYP3A substrate was investigated. Use of either total (bound + unbound) or unbound AUC showed a high relationship with the *in vivo* data, accompanied with a correlation coefficient (R^2) of 0.859–0.863. Kaneko *et al.* [165] demonstrated a large lot-to-lot variation in the $E_{\max}$ and EC_{50} of CYP3A induction in HepaRG cells. The variation in induction response appeared smaller at the low exposure of inducers or positive control than at the high exposure in the dose–response curve. To minimize the variation, an index value termed the *relative factor* (RF) was introduced and is defined by the ratio of the minimum concentration to cause induction response of the inducers tested to the positive control such as rifampicin or phenobarbital. It was revealed that the ratio of the *in vivo* unbound plasma concentration of inducers toward the RF values was a good indicator to classify into three categories: low, medium, and high potency.

In contrast to qualitative assessment using constant inducer concentration or AUC, quantitative prediction of the extent of induction of CYP3A4 was performed based on time-dependent mass balance of CYP3A4 protein calculated by the $E_{\max}$ model incorporating the data in reporter gene assay and plasma concentration profile of inducers simulated by the one-compartment model [197]. The predicted induction ratio was related to urinary metabolite ratio of 6 β -hydroxycortisol/cortisol before and after treatment of CYP3A4 inducers.

Prediction approaches have been developed for each mechanism of DDI: reversible, irreversible inhibition, and induction. The method that focuses on a single interaction mechanism is likely to, in some cases, produce misleading predictions of compounds with multiple mechanisms such as ritonavir characterized as an irreversible inhibitor and inducer of CYP3A4. Fahmi *et al.* [198] has developed a more comprehensive mathematical model for simultaneously evaluating the effect of multiple mechanisms of CYP3A4-related DDI. Utilizing this model, DDI arising via inactivation (e.g., erythromycin), competitive inhibition (e.g., ketoconazole), or mixed mechanism (e.g., ritonavir) was well predicted within the ranges reported in clinical studies. The geometric mean fold errors were somewhat decreased by the combined DDI model. The integrated prediction model produced a success rate of 88%, which was comparable to that predicted by DDI functions in the computational PBPK model such as SIMCYP® [199].

12.6 FUTURE PERSPECTIVE

A great need for efficient identification of NMEs with desirable pharmacokinetic profiles has enhanced the efficiency of lead optimization processes based on metabolic stability, CYP inhibition, and induction, coupled with a paradigm shift from throughput to quality. By this trend, the development of high quality screening systems that can be more relevant to *in vivo* humans is needed. In the fine tuning of chemical structures that have an important position in the optimization process to create NMEs, the utilization of human hepatocytes has enhanced the quality of the data in the study of metabolic stability, CYP inhibition, and induction, but the demand for high quality hepatocytes applicable to those studies heavily outweighs the availability. Si-Tayeb *et al.* [200] imply the possibility that human induced pluripotent stem (iPS) cells will be used as a source of hepatocytes for toxicological and drug metabolism studies. The use of iPS cells has required the establishment of culturing conditions using microengineering approaches that support expression of a full panel of phase I and II enzymes and transporters. More recently, an advanced technology with transient overexpression of hemeobox gene using adenovirus vector allowed for differentiation of human iPS cells to hepatocytes, which successfully displayed CYP3A4 induction activity by rifampicin. Efficient generation of the hepatocytes from iPS cells would show a high possibility of giving an evolutionary change in the CYP induction study [201].

Furthermore, chromosome engineering techniques, which are based on transfer of a large size of chromosome with a defined region, have enabled to produce humanized model animals. The human chromosome 7 region around CYP3A locus was cloned into the SC20 vector. It is interesting to note that transcript of CYP3A gene was also detected specifically in the liver and small intestine of SC20-transferred chimeric mice, which is coincident with the tissue specificity of CYP3A expression in humans [202,203]. There has been possibility that HAC-mediated gene expressions of human drug metabolism enzymes in transgenic animals produce animal models to study drug metabolism and predict DDI-associated events in humans. Those *in vitro* and *in vivo* assessment tools will be a breakthrough in pharmacokinetic studies in drug discovery and development.

It has been revealed that multiple mechanisms such as transporter-mediated liver uptake and efflux and drug metabolism influence CYP inhibition and induction. Accordingly, using those human-relevant *in vitro* data, the selection of NMEs with high developability among the candidates will be routinely conducted based on the predicted pharmacokinetic profiles and the evaluated possibility of DDI by comedication in humans through utilizing a whole-body PBPK model incorporating those multiple mechanisms.

14.1 SUMMARY

Monoclonal antibody (MAb)-based methods are ideal reagents for cytochrome P450 (P450) research. The properties and molecular diversity of P450s make them extraordinarily suitable for investigation with MAbs. The P450s are present in multiple forms. Defining the role of each P450 isoform for drug metabolism in human liver microsomes (HLM) *in vitro* requires a method that is both highly specific and highly inhibitory to P450 activity and thus can identify and quantitate the contribution of single or several P450 isoforms that metabolize the drug. MAbs have been isolated that are inhibitory and specific to 13 human P450s. The MAbs may also be used to determine the role of each P450 isoform for a variety of nondrug metabolizing activities such as mutagenesis carcinogen S9 activation and binding to DNA and others described in the text.

14.2 INTRODUCTION

Our laboratory has produced highly specific and inhibitory MAbs to human P450 1A1, 1A2, 2A6, 2B6, 2C8, 2C9, 2C19, 2C Family (8, 9, 18, 19), 2D6, 3A4/5, 2E1, and 2J2. The MAb system identifies drugs metabolized by a single P450, multiple P450s, and alleles of polymorphic P450s. The MAbs may be used to measure the expression of specific alleles of polymorphic P450s as well as the formation of specific optically active metabolites of racemic mixtures. The *in vitro* assay system uses HLM from different individuals for the metabolism of the drug. The MAbs are added either singly or several combinatorially to determine potential interactions in the metabolism of a drug by two or more P450s. MAbs display extraordinary specificity, far greater than that of polyclonal antibodies or chemical inhibitors, which ordinarily are considerably cross reactive. We have used MAb-based analysis to examine the role of different P450 isoforms for diazepam metabolism, taxol metabolism, coumarin hydroxylation, and dextromethorphan metabolism by 2D6 and 2C9.

14.3 MONOCLONAL ANTIBODY (MAb)

14.3.1 Monoclonal Antibodies: Production

MAbs are produced by the “hybridoma” technology [1,2]. Their discovery is a major achievement of modern biology. The hybridoma technology grew out of the clonal selection hypothesis of Burnet and colleagues [2], which states that each B-lymphocytes antibody-forming cell and its progeny is committed to the production of a single type of antibody molecule. The MAbs are chemically defined reagents that recognize a single antigenic determinant or “epitope” on a macromolecule [2]. This specificity continues for the lifetime of the cell and its progeny.

For the production of MAbs [3], myeloma tumor cells are fused with the isolated dissociated B-lymphocytes of the spleen from mice immunized with a particular immunogen. The fused cells or “hybridomas” exhibit unique and special character by combining the characteristics of the B-lymphocytes that are committed to the continuous and stable production of a specific antibody with the myeloma tumor cells imparting immortal properties to the hybridoma cells. The individual hybridomas are cloned and screened for the desired MAb. The screening is done by a variety of methods including binding assays, Western blots, and enzyme inhibition. The selected clone and its progeny produce identical antibodies directed to a single epitope. The selected clones are usually subcloned three times to assure monoclonality. These hybridomas, grown in cultures in a defined medium, produce the chemically defined MAbs free of contaminating cells and protein debris. Large amounts of MAbs can be obtained by injecting the hybridomas into the peritoneal cavity of appropriate recipient mice, where they grow as ascites tumors and produce large quantities of the specific MAb. The MAb-producing hybridomas are essentially immortal and can be frozen and stored or grown in culture indefinitely.

14.3.2 MAbAnalytic Systems: Liver Microsomes

Comprehensive reviews of the value and utility of MAbs for the study of drug metabolism have been published [4,5]. MAbs were first made to rabbit [6] and rat

P450s [7]. Table 14.1 shows the MAbs that are P450 isoform specific and are >90% inhibitory to the expressed target P450 activity. Some, but not all the MAbs also immunoblot the target P450 (Table 14.2). The amount of inhibition of drug metabolism *in vitro* by HLM with the addition of the specific MAb quantitates the contribution of the target P450 to the metabolism of the drug. The MAb method is in stark contrast to other complex analytic systems that are relatively nonspecific and currently being

used to study drug metabolism. Drugs metabolized by a single P450 isoform or metabolites formed from a single metabolic pathway may be useful as markers for identifying the target P450 *in vivo*. The MAb methodology is precise, simple, and highly reproducible. The MAbs, which are highly specific and highly inhibitory, may also be used to measure the specificity and the potency of chemical inhibitors.

14.3.3 Monoclonal Antibody and Human Liver Microsomes Analytic System

Figure 14.1 shows production and analytic system of MAbs. Specific inhibitory MAbs identify individual P450s responsible for drug metabolism in HLM *in vitro*. The MAb system analyzing HLM identifies the P450 isoforms that catalyze the metabolism of the drug substrate and quantitates the maximum contribution of each P450 for the metabolism of the drug. The MAb system uses saturating levels of both the MAb and the drug substrate using zero-order kinetics for the reaction, and thereby defining the maximum contribution of each P450 isoform to the metabolism of the drug. The system also identifies drugs that are metabolized by a single P450, two or more P450s, and polymorphic P450s. The drugs metabolized by a single P450 have potential for use as markers identifying the presence and the activity of the target P450 *in vivo*. The MAbs also identify the P450s catalyzing metabolism in alternative pathways, yielding metabolites that may be used as *in vivo* markers for specific P450s. The system can study polymorphic P450s, examine the metabolic consequences of an absent or deficient polymorphic P450 in individual microsomes, and identify other active nonpolymorphic P450s that can reduce the deleterious effect of the missing or deficient isoforms. The methodology of the MAb system is simple. Basal control levels of metabolism of the drug are measured, and the amount of inhibition of metabolism on the addition of the isoform-specific inhibitory MAb determines the quantitative role of each P450 for the metabolism of the drug. The MAb system of analysis of HLM metabolism is entirely self-contained, and the values obtained are the results of diverse elements such as interindividual differences in the amount and activity of the target P450 as well as factors such as lipid and cofactor content, P450 protein structural configuration, membrane–enzyme interactions, and other currently unknown factors. Table 14.1 is a list of the human cytochrome P450 enzymes for which MAbs have been made in the Laboratory of Metabolism, National Cancer Institute. These are MAb 1-7-1,

Figure 14.1 Monoclonal antibodies to human cytochrome P450s (preparation and assay).

which inhibits both 1A1 and 1A2 in rat livers but is specific only to 1A1 in human tissues [8]. The MAb 1-7-1 has also been used to phenotype 1A1 in different human tissues [9] and phenotype differences in single and twin human placenta [10]. Anti-P450 MABs have been made to 1A2 [11], 2A6 [12], 2B6 [13], 2C8, 2C9, 2C19, 2C [14,15], 2D6 [16,17], 2E1 [18], 2J2 [19], and 3A4/5 [20]. One of the MABs, 1-68-11, binds and inhibits each of the 2C8, 2C9, and 2C19 isoforms of the P450 2C family, indicating that they share a common epitope. Table 14.1 also shows the Ig type of each of the MABs and their inhibitory activity toward the expressed P450 isoform, which was >80–90%. The last column of Table 14.1 lists the substrates that were used to measure the inhibitory activity of each MAB to the expressed P450.

14.4 IMMUNOBLOTTING MABs

Table 14.2 lists nine MABs that immunoblot the target P450. There are large interindividual variations in the protein content as well as enzyme-inducible activity of the

different P450s. The immunoblotting MAbs can be used to determine the protein amount of a specific P450 in human tissues [13] and measure interindividual differences of different populations. The immunoblotting MAbs have also been used in immunohistochemical studies. A noninhibitory MAb, anti-P450 1B1, has been used for the immunohistochemical localization of 1B1 in breast cancer [21]. The MAb anti-rat P450 2E1 has been used for immunohistochemical studies of murine lung [22] and for studies on the effects of acetone and ethanol in murine liver [23]. Among other functions, P450 2J2 metabolizes arachidonic acid and is involved in calcium regulation in cardiomyocytes [19].

14.5 MAb PROPERTIES

14.5.1 Monoclonal Antibodies and Epitope Specificity

The specificity of the MAb resides in its precise ability to recognize and bind a specific epitope on the surface of a P450. Thus, an MAb may recognize only a single species of P450 if it contains a unique epitope. In this case, the MAb would be specific for only a single isozymic form of P450. AnMAb that recognizes an epitope that is present in more than one form of P450 will bind all of those forms of cytochrome P450 containing the common epitope. On theoretical grounds, a comprehensive MAb library will contain MAbs that recognize single unique forms of P450.

14.5.2 Monoclonal Antibody Allele Specificity

Table 14.3 demonstrates the allele specificity potential of a MAb. MAb 292-2-3 specifically binds to a single allele, P450 2C9*2(Arg₁₄₄Cys), of three expressed P450 2C9 allozymes (*1,*2,*3). This MAb does not bind the 2C9*1(Arg₁₄₄) wild type or the third allele P450 2C9*3(Ileu₃₅₉Leu) [24]. Of the three alleles of P450 2C9, the wild type and two polymorphic alleles have only a single amino acid substitution relative to the wild type and differ from the wild type by a single amino acid, and thus MAb

TABLE 14.3 MAb Allele Specificity

Allele		Tolbutamide	Diclofenac
2 C9*1 Arg ₁₄₄	Control	1.0 ^a	0.30
	+MAb	0.98	0.30

MAb 292-2-3 inhibits only the single allele 2C9*2 arg₁₄₄cys catalyzed tolbutamide and diclofenac metabolism.

^aActivity (mmol product/min/nmole P450).

292-2-3 detects a single amino acid substitution. MAb 292-2-3 inhibits the P450 2C9*2 allozyme-catalyzed metabolism by 96% and shows no inhibition of the wild type P450 2C9*1 metabolism. The P450 2C9*2 allozyme-specific MAb does not bind to any of the other P450 2C9 isoforms, 2C8, 2C18, or 2C19, or any of the other human P450s, 1A1, 1A2, 2A6, 2B6, 2D6, 2E1, or 3A4/5. The MAb 292-2-3 inhibits the metabolism of tolbutamide, diclofenac, and phenanthrene by the P450 2C9*2 by >90% and does not inhibit the enzyme activity by the other two alleles or any of the other human P450 isoforms listed above. The MAb 292-2-3 can be viewed as a prototype of an ideal and extraordinary specific reagent for the detection and measurement of the metabolic role of highly related isoforms and polymorphic alleles of human cytochrome P450 [24].

14.5.3 Monoclonal Antibody Enantiomer Specificity

Phenprocoumarin is a potent anticoagulant in common usage and is hydroxylated by the P450s of the 2C family. One route of metabolism converts the drug to both the *S*-4-OH and to its enantiomeric *R*-4-OH (Table 14.4). The MAb specific to P450 2C8 inhibits the formation of the *R*-enantiomer and does not inhibit the formation of the *S*-enantiomer. The MAb to P450 2C9 also shows enantiomer specificity, inhibiting the *R*-4-OH formation and not inhibiting the *S*-4-OH formation [25]. The MAb anti-P450 2C9 also exhibited enantiomer selectivity. P450 2C9 catalyzes the demethylation of the endocrine disrupter pesticide methoxychlor, forming a chiral product [26]. The HLM generates primarily the *S*-mono OH form. The MAb anti-2C9 selectively reduces the formation of the *S*-form from 80% to 55%, thereby enantiomer selectively changing the ratio of the *S*- and *R*-enantiomers formed. This study also found that expressed P450 2C19 exhibited the highest level of activity for demethylation but was not inhibited by MAb anti-2C19 in HLM, thus indicating that P450 2C19 is not active in HLM. These unusual results suggest that with certain substrates (e.g., methoxychlor), there is no correlation between the expressed enzyme activity (in this case, P450 2C19) and its presence in HLM. MAbs have also been used to study the mechanism of toxicity of the chemotherapeutic agent ifosfamide, which is believed to be due to its conversion to nephrotoxic chloroacetaldehyde [27]. The study showed that metabolism of ifosfamide was catalyzed by P450 3A4 and 2B6, both of which are present in fetal, pediatric, and adult tissues. The P450 3A4 and 2B6 were found in the fetus as early as eight weeks of gestation. Thus, the MAb system can easily map the tissue distribution of P450 isoforms in fetal as well as adult tissue and help to clarify the mechanism of toxicity of chemical agents.

14.6 SINGLE AND COMBINATORIAL ANALYSES

Table 14.5 shows the MAb-based analysis of 7-ethoxycoumarin deethylase activity using purified MABs added singly to the reaction mixture compared to analysis with a combinatorial system. The values obtained using the single MAB addition for measuring the contribution of P450 2E1, 2A6, 2B6, and 1A2 corresponded well with values obtained for the same four P450s using the combinatorial analysis with MABs against each of the four P450s. The combinatorial system permits the concurrent analysis of the contribution of up to four different P450s. Table 14.6 is a summary of the interindividual differences in the activity of four different HLM comparing the single and combinatorial systems. There was wide variability in the basal activity of the different HLM samples. The largest approximate amount of activity was due to P450 2E1 and 2B6. P450 2B6 activity ranged from 11% to 50%, P450 2E1 from 16% to 57%, P450 1A2 from 7% to 22%, and P450 2A6 from 8% to 32%. Table 14.6 uses ascites fluid as the MAB source, which, in comparison, is similar to the data in Table 14.5 using the purified MABs. These values could not be determined by simply using the expressed P450 system for analyses. The enzyme activities exhibited by expressed P450 isoforms do not accurately reflect their activities in the HLM and obviously cannot be used to examine interindividual differences. However, the expression system is valuable for identifying P450s that exhibit enzymatic activity toward a given drug substrate. The presence of high activity of an expressed isoform may be a presumption but not a certainty indicating the presence of the isoform activity in HLM. Figure 14.2 shows a combinatorial analysis of diazepam hydroxylation to temazepam (TMZ). For this figure, the height of each column is compared to the height of the previous column. No difference in the height of the adjacent column indicated that the P450 isoform of the second column does not contribute to the reaction. The MABs anti-2B6 and anti-3A4 were combined for convenience with the previous knowledge that P450 2B6 is inactive for TMZ formation. P450 3A4 is the only isoform that exhibits metabolic activity for TMZ formation. The amount of activity exhibited by 3A4 ranges from 90% in HLM 80 to 70% in HLM 79. P450s 2C8, 2C9, and 2C19 exhibit no activity. In contrast, Fig. 14.3 shows the variable contribution in eight HLM of four P450 isoforms for the N-demethylation of diazepam to nordiazepam (NDZ). The large interindividual variation is reflected by the contribution of P450 3A4/2B6 activity, which ranges from

^aMAb in ascites fluid.

20% to 80%, and the large variable contribution from P450 2C9 ranges from 10% to 46% and 3–30% from P450 2C8. There is little or no contribution from P450 2C19. It is important that a significant number of samples of HLM be examined in these studies. These data are also summarized in Table 14.7.

14.7 DRUGS METABOLIZED BY A SINGLE P450

Taxol 3'-hydroxylation is catalyzed solely by P450 3A4/5, and there is relatively constant inhibition of 6-hydroxy formation by MAb anti-2C8 (Table 14.7), which indicated that there is relatively little interindividual variation in the nine HLM samples for taxol 6-hydroxylation catalyzed by P450 2C8. Table 14.7 shows that coumarin hydroxylation is catalyzed entirely by P450 2A6 and thus would be an excellent drug substrate marker for the *in vivo* presence of P450 2A6. The MAB system also determines the role of each P450 isoform for the metabolism of a drug through alternate metabolic pathways, such as is the case with diazepam and taxol. When a metabolite of a drug is the result of the activity or affinity of a single P450,

Figure 14.2 MAb combinatorial analysis of diazepam hydroxylation in human liver microsomes. The difference between each bar represents the amount of P450 activity contributed by the subsequent addition of the indicated MAb. Results are the average of duplicate incubations. Values in parenthesis are control activity.

the metabolite identifies the P450 isoform as a potential marker for the *in vivo* presence of the P450 isoform. Metabolite analysis for taxol 6-hydroxy and taxol 3-hydroxy formation catalyzed solely by P450 2C8 and 3A4 would be excellent markers for the *in vivo* presence of P450 2C8 and 3A4, respectively. Likewise, coumarin hydroxylation that is metabolized solely by 2A6 would be an excellent marker for 2A6 activity *in vivo*. There are two extensive reviews [28,29] on the use of probe drug substrates for the *in vivo* targeting of a P450 isoform for its role in the metabolism of a drug. A primary concern for this method is the specificity of the probe drug and the potential contribution of low activity isoforms to the reaction *in vivo*. In many cases, the specificity of the probe, substrate has not been determined for either the metabolism of the drug or the formation of marker metabolites arising from alternate markers must be responsible for essentially the entire metabolism of the drug, and minor P450s should not contribute to the reaction. Minor isoforms exhibiting activity for drug metabolism may cause a misreading of the identification of the *in vivo* target P450. Combinatorial analysis of diclofenac 4-OH formation indicates that the P450 2C9 is the primary and major catalyst for diclofenac hydroxylation. Minimal or very slight activity is shown by other members of the P450 2C family. Table 14.8 indicated that in 10 HLM, 83–88% of activity was due to P450 2C9, and 7–8% was contributed by P450 2C19. The activity of the expressed P450s for hydroxyl tolbutamide formation shows that two alleles of P450 2C9, 2C9*1, and 2C9*2, show high activity, with P450 2C9*2 exhibiting half the activity of the wild type. P450 2C19 exhibits moderate activity, and little or no activity is shown by the other expressed P450s—2C8, 2C18, and 2D6. Table 14.8 shows that in eight HLM, P450 2C9 contributes 77–82% of tolbutamide 6-hydroxylation activity with variable low contributions of about 5–10% from 2C8 and 2C19. Table 14.8

contributed by 2C9. However, when the MAb anti-2C19 was added before the addition of the MAb anti-2C19, the 2C9 showed significant activity (20–25%). These results suggest that there may be competition for certain substrates by two or more P450 isoforms. Minor or moderate contributions of activity from P450 isoforms other than those responsible for the major amount of metabolism may seriously limit interpretation and cause a misreading of the role of different P450s *in vivo*. This is especially true when there is large interindividual variability in microsomal P450-catalyzed metabolism.

14.8 ADDITIONAL MAb FUNCTIONS

14.8.1 Polymorphisms

The first P450 polymorphism found to have clinical significance was the discovery of the 2D6 polymorphism. Dextromethorphan metabolism has been used as primary marker of P450 2D6 activity. Figure 14.4 is a combinatorial analysis of dextromethorphan metabolism in eight HLM. The MAb-based analysis indicated that in individuals polymorphically deficient in 2D6 activity, the P450 2C9 partially replaces the absent 2D6-catalyzed metabolism and catalyzes up to 50% of the total dextromethorphan metabolism. A parallel analysis of bufuralol metabolism with the same eight HLM in Fig. 14.4 showed that in the MAb anti-2D6-based analysis of the same eight HLM, in six of the eight HLM, 2D6 metabolized 80–90% of bufuralol metabolism. The two HLM deficient in 2D6 metabolism of dextromethorphan were also deficient in bufuralol hydroxylation. In these two HLM, 1A2 showed no activity, 2C9 contributed 15–25% activity, and 2C8 showed 10–40% activity. Specific and inhibitory MAbs have been used in a variety of studies. To cite several examples, MAbs have been used to identify the human P450s responsible for the *in vitro* formation of *R*- and *S*-norfluoxetine [30]. MAbs have also identified P450 2C8 and 3A4 as the principal enzymes involved in the metabolism of the insulin secretagogue repaglinide [31]. P450 2D6 and 3A4 were found responsible for hydrocodone oxidation [32]. A variety of environmental agents, including acylether, nicotine, *N*-nitrosoethylamine, and *N*-nitrosobenzyl-methylamine, are metabolized by P450 2A6 [33]. Propofol is metabolized by P450 2B6 [34]. P450s 3A4 and 2C9 are responsible for the metabolism of 17 α -ethinylestradiol [35]. It would be useful to have a comprehensive array of MAbs to all the enzymes of phase II drug metabolism. However, that would be difficult to attain because the conjugating enzymes UDPGT, GST transferase, and sulfotransferase all have numerous different isoforms, and phenotyping an individual with a large array of MAbs to each isoform would be very difficult.

14.8.2 Endobiotic Metabolism

Table 14.9 shows the metabolism of endobiotics and nondrug xenobiotics responsible for chemical toxigenesis. Table 14.9 shows that in 18 HLM samples, P450 3A4/5 was responsible for 72–86% of testosterone 6- β -hydroxy formation. Table 14.9 also shows an analysis of the metabolism of three xenobiotics. In 18 HLM samples, 32–60% of chlorzoxazone metabolism was catalyzed by P450 2E1 and 16–46% of nitroanisole metabolism was metabolized by P450 2E1. In 18 HLM samples, 74–86% of the

MAbs were added singly (a) or in combinatorial succession (b). Results are the average of duplicate incubations. Values in parenthesis are control activity.

metabolism of the potent carcinogen aflatoxin was metabolized by P450 3A4. The analysis of the metabolism of chlorzoxazone and nitroanisole was incomplete because the role of other P450s was not defined.

14.9 OTHER METHODS OF MICROSOMAL ANALYSIS

14.9.1 Specificity and Potency of Chemical Inhibitors

Chemical inhibitors have been used extensively to identify the role of different P450 isoforms in the metabolism of a drug. The chemical inhibitors are generally selective and do not display the specificity of the MAbs that is required to target and

quantitate the role of a P450 isoform responsible for a drug's metabolism. Chemical inhibitors have been used rather extravagantly, with little attention to their lack of isoform specificity. The MAb system can be used to assess both the potency and the specificity of a chemical inhibitor. The MAb-based analyses were used to evaluate the chemical inhibitors, ketoconazole, orphenadrine, and quinidine, which are commonly used as inhibitors of P450 3A4, 2B6, and 2D6, respectively. Ketoconazole at 100 μM inhibits the metabolism of phenanthrene by 80%, indicating the participation of P450s other than 3A4. The ketoconazole inhibitor does not identify all the other P450s responsible for phenanthrene metabolism. Quinidine is thought to be a P450 2D6-specific inhibitor, and debrisoquine metabolism is generally used as a P450 2D6-specific marker. However, a report found that debrisoquine is also metabolized by P450 1A1, and the metabolism is inhibited by quinidine [36]. Thus, neither ketoconazole nor quinidine is a specific inhibitor of P450 3A4 or 2D6, respectively. Orphenadrine is commonly used as a P450 2B6 inhibitor. The MAb system was used to measure the relative potency of orphenadrine compared to the specific inhibitory MAb anti-2B6. Phenanthrene metabolism was inhibited by 60% by the MAb anti-2B6, whereas 100 μM orphenadrine inhibited the reaction by only 25%, indicating its relatively poor inhibitory potency of orphenadrine compared to the inhibitory anti-2B6 MAb. Thus, the specific MAbs can be used to analyze both the specificity and potency of a chemical inhibitor. A different study examined the specificity of inhibition of expressed P450 with eight commonly used chemical inhibitors [37]. Ketoconazole and quinidine exhibited similar high inhibitory activity toward P450 3A4 and 1A1, sulphenazole showed selectivity for P450 2C9, and α-naphthoflavone (ANF) inhibited both P450 1A1 and 1A2. The remaining inhibitor selectivities were at best moderate. The major advantage of the MAbs compared to chemical inhibitors is the extraordinary specificity of the MAbs. Some of the chemical inhibitors, such as ketoconazole, can be highly selective

but not specific for a target P450. However, a major advantage of a highly selective chemical inhibitor, such as ketoconazole, is the ability to administer the inhibitor to the patient. That is not possible with the MABs because they cannot be administered *in vivo*. Thus, chemical inhibitors can be used to alter routes of metabolism and metabolic pathways that would be therapeutically advantageous.

14.9.2 Monoclonal and Polyclonal Antibodies

MABs derive their single-epitope specificity by being formed from a single MAB produced by a parent spleen cell. The MAB-producing spleen cells are immortalized by fusion with myeloma cells, producing hybridomas that maintain their single-epitope specificity. The hybridomas are stable and continuously produce identical MABs that can be used universally and are transferable to any laboratory as pure reagents. In contrast, polyclonal antibodies commonly display cross-reactivity because they are heterogeneous mixtures of monoclonals that, by definition, vary with each immunization, even when using pure immunogens. Undefined polyclonal antibodies resulting from independent immunizations require extensive purification and characterization to eliminate potential and undesirable cross-reactivity. The major advantage of polyclonal antibodies is the relative simplicity of their production compared to the isolation of highly specific and highly inhibitory MABs to target specific P450 isoforms. The hybridomas producing MABs are essentially immortal and produce identical MABs with an identical epitope-binding character. Experimental results with polyclonal antibodies from different laboratories are not comparable because the polyclonal antibodies are epitopically different and may have different cross-reactivity. Thus, the MABs are more reliable reagents than the polyclonal antibodies.

14.10 MULTIFUNCTIONAL CYTOCHROME P450

Cytochrome P450 is multifunctional and the MAB technology can be successfully applied to the study of a variety of diverse functions of P450 and within each system identify the P450 isoform responsible for the observed biological activity (Table 14.10). The MAB system can be used to map the protein amount and subcellular content and the activity of individual P450s in different human tissues. For each tissue or cell, the inhibitory MABs may define the amount of P450-specific enzyme activity present and the immunoblotting MABs measure the P450 isoform protein amount. The MAB system demystifies the "S9" used commonly for activation in the Ames mutagen detection system [38], an activation system previously described for the covalent binding of benzopyrene to DNA [39]. The activity of the "S9" is microsomal and a function of the heterogeneous mixture of P450 isoforms in the microsome-derived "S9" [39]. The MABs can identify those isoforms responsible for the "S9" activity. The MAB system identifies the individual P450s that catalyze the conversion of compounds to electrophiles that are mutagenic [40,41] or to active metabolites that covalently bind to DNA and protein. The MAB system identifies the P450 isoforms that convert environmental agents to mutagenic, carcinogenic, toxic, and immunotoxic metabolites. The MAB system may identify the function of each P450 in the metabolism, induction, and

inhibition of P450 activity by neutraceuticals, natural products, and other environmental chemical agents. The MAb system may also identify the expression of different P450 isoforms in cells grown in a variety of cell culture systems.

14.11 SYNOPSIS AND CRITIQUE (DRUG METABOLISM)

Different methods have been used to identify and quantitate the role of each P450 for the metabolism of a drug [42,43]. One method is the measurement of the enzyme activity of the expressed pure P450 toward specific substrates. The amount of substrate metabolized by the pure expressed enzyme determines its capability to metabolize the substrate, but it is often not a good indicator of a role of the P450 isoform for *in vitro* microsomal metabolism. The P450 expression method does not take into account different amounts of the P450 isoform protein present in HLM and its usual large interindividual variability. The HLM analysis of a P450 isoform activity depends on the P450 protein content and other factors, such as cofactor and lipid content, membrane and structural positioning, and potential for competition with P450 isoforms that may also metabolize the subject drug. Drug therapeutics and drug discovery would be promoted if drugs or combination of drugs were available or developed that would be designed specifically for highly reliable phenotyping of the patient. Knowledge of the patient's phenotype would greatly enhance the ability of the clinician to reduce adverse drug reactions and administer effective drugs or combination of drugs at the right dosage by having a precise knowledge of the patient's phenotype for the metabolism of the drugs. The MAb method is in stark contrast to other complex analytic systems that are relatively nonspecific and currently being used to study drug metabolism. The MAb system identifies and quantitates drugs metabolized by a single P450, multiple P450s, and polymorphic P450s. Drugs metabolized by a single P450 isoform or metabolites formed from a single metabolic pathway may be useful as markers for identifying the target P450 *in vivo*. The MAb methodology is precise, simple,

and highly reproducible. The MAbs, which are highly specific and highly inhibitory, may also be used to measure the specificity and the potency of chemical inhibitors.

The MAbs will prove useful for identifying and quantifying P450 proteins that vary under different conditions, which include nutritional and hormonal states, developmental stages, age, sex, and inducer exposure. A full library of MAbs to P450 could develop a P450 taxonomy and would greatly enhance the progress of P450 research.

14.12 CONCLUSION

This chapter evaluated the efficacy of the various methods used to examine the role of P450 isoforms for the metabolism of a drug. The conclusion of this analysis was that specific and potent inhibitory MAbs against the different P450 isoforms (such as those listed in Table 14.1), which are characterized for specificity and inhibitory potency and verified with HLM and the expressed P450, represents the most valuable approach and basically the only method necessary for a phenotyping study.

15.1 SUMMARY

Induction of the drug-metabolizing enzymes, in particular, cytochrome P450 (CYP) forms, is a major cause of drug–drug as well as herb–drug interactions that can lead to adverse side effects, which may prove fatal. As a result, an integral part of drug development is to ascertain whether it has the potential to act as an inducer of CYP and other enzyme systems in order to avoid serious drug interactions with coadministered drugs. Moreover, for both drugs and other chemicals, CYP induction may be associated with adverse toxicology including tumorigenesis.

A versatile *in vitro* model system that can be employed to evaluate the effect of chemicals on xenobiotic-metabolizing enzymes is the precision-cut tissue slice procedure. Slices from liver as well as extrahepatic tissues such as the kidney, lung, and

intestines have been utilized to identify metabolic pathways and assess the toxicity of chemicals, including their potential to induce xenobiotic-metabolizing enzyme systems. Many studies have utilized precision-cut rat liver slices to monitor the induction of enzymes belonging to the CYP1–CYP4 families. A wide range of chemicals have been studied using this *in vitro* system, including drugs, environmental contaminants, and phytochemicals. CYP form induction has been determined by measurement of appropriate enzyme activities (EAs) (either in intact slices or in slice homogenates/subcellular fractions), protein levels (e.g., by Western immunoblotting), or mRNA levels. Established inducers of various CYP enzymes upregulated CYP enzymes as would have been envisaged on the basis of *in vivo* studies reported in the literature. In human liver slices, the induction of a number of CYP forms including CYP1A1, CYP1A2, CYP2A6, CYP2B6, CYP2C9, CYP2C19, and CYP3A4 has been demonstrated.

As with the induction of CYP forms, a wide range of compounds have been shown to induce phase II xenobiotic-metabolizing enzymes, including epoxide hydrolase, UDP-glucuronosyltransferase (UGT), sulfotransferase, and glutathione *S*-transferase (GST) forms, in cultured rat liver and lung slices, and human liver and intestine slices.

Finally, procedures have been developed for the successful cryopreservation of precision-cut liver slices from various animal species, which can also be used to assess the potential of xenobiotics to induce the xenobiotic-metabolizing enzyme systems.

15.2 INTRODUCTION

The use of precision-cut tissue slices is increasingly gaining acceptance and is utilized worldwide to provide answers in studies concerned with the metabolism and toxicity of chemicals [1–5]. The major “competing” *in vitro* system involves the use of isolated cells such as hepatocytes. However, precision-cut slices offer some important advantages over the use of isolated cells that cannot be ignored, and these are summarized below.

- Compared to single cell preparations such as hepatocytes, slices function as “mini” tissues, maintaining the functional heterogeneity of the parent tissue and permitting the study of zonal effects. Moreover, in tissues such as lung that has a heterogeneous cell population where drug or xenobiotic-metabolizing EAs are present only in some cell types [6], the use of slices allows the identification of cell-specific toxicity.
- The procedure for isolation of single cells employs digestive enzymes that remove cell-to-cell contact, thus preventing cellular communication and interactions, and lead to the collapse of tissue architecture. Such communication is preserved in slices and, furthermore, maintenance of tissue architecture in slices makes possible the use of morphological endpoints, such as histology and immunocytochemistry, in evaluating xenobiotic toxicity.
- Generation of slices using an appropriate tissue slicer (e.g., a Krumdieck or Brendel-Vitron slicer) is rapid and causes only minimal damage to the tissue and does not necessitate the use of detrimental proteolytic enzymes that are routinely utilized in cell isolation.

- The use of slices facilitates comparisons of the metabolism and/or toxicity between animal species, including human, and tissues, especially as slices can be successfully cryopreserved (see below), which would not be otherwise possible. Such cross-species comparisons can provide invaluable information, enabling the identification of animal species that would be appropriate surrogates for human in toxicological evaluation studies.
- Slices from different tissues may be cocultured so that, for example, the sequential metabolism and toxicity of xenobiotics can be delineated.

15.3 CLINICAL AND TOXICOLOGICAL IMPLICATIONS OF ENZYME INDUCTION

In an era where polypharmacy has become routine, it is inevitable that coadministered drugs were shown to interact with adverse or even fatal consequences for the patient. The induction of the drug (xenobiotic)-metabolizing enzymes by one or more administered drugs is a major mechanism underpinning many such interactions. In most instances, enzyme induction involves the stimulation of CYP forms that are present in the liver and extrahepatic tissues [7,8]. The most important microsomal CYP forms involved in the metabolism of therapeutic agents in human liver include members of the CYP1A, CYP2A, CYP2B, CYP2C, CYP2D, CYP2E, and CYP3A subfamilies [7–12]. Such drug interactions often involve CYP3A4, as this enzyme is the most active human CYP form in drug metabolism and, moreover, is the dominant form in the liver and intestine, the principal site and the first site of metabolism following oral drug intake, respectively. There are numerous examples of drug–drug interactions consequential to CYP induction [9–12]. Patients with transplanted organs and successfully stabilized on the immunosuppressant cyclosporin displayed signs of rejection after self-medicating with St. John's wort, a herbal remedy taken to treat mild depression [13]. It appears that a component(s) of this remedy elevates CYP3A4 activity, leading to enhanced cyclosporin metabolism resulting in suboptimal plasma levels of the drug and, consequently, tissue rejection. Since the norethindrone and ethinyl oestradiol components of the contraceptive pill are also deactivated by CYP3A4, intake of St. John's wort has also been associated with intracyclic bleeding episodes as a result of contraceptive failure [14,15]. The treatment of humans with the antibacterial agent rifampicin (RIF), which induces CYP3A and other CYP forms, has been shown to produce a number of clinically important drug–drug interactions [10–12]. These include cyclosporin (reduction in blood levels leading to transplant rejection), warfarin (reduced prothrombin time), oral contraceptives (unplanned pregnancies), and human immunodeficiency virus protease inhibitors such as ritonavir and indinavir (reduced systemic exposure leading to a diminished antiretroviral effect).

The treatment of rats and mice with therapeutic agents and other chemicals, which induce hepatic microsomal CYP forms may be associated in chronic studies with the formation of tumors in the liver and other tissues [12]. For example, CYP2B inducers can give rise to liver and thyroid gland tumors and exposure to CYP4A inducers can lead to tumor formation in the liver and testis. In these instances, the induction of rodent hepatic CYP forms represents just part of a pleiotropic response to such compounds. However, the induction of CYP forms can serve as a biomarker for

potential subsequent tumor formation, and hence it is important in the toxicological evaluation of new chemical entities (NCEs).

As a result of the potential clinical and toxicological consequences of CYP enzyme induction, studies to screen for such an effect form an integral part of drug development. Studies encompassing a large number of doses, that would not be feasible to conduct *in vivo*, can be readily performed *in vitro* using precision-cut tissue slices from laboratory animals and human donors.

15.4 PREPARATION AND CULTURE OF PRECISION-CUT TISSUE SLICES

Tissue slices can be prepared from the liver and extrahepatic tissues such as the kidney, lung, and different parts of the intestine [1–5]. For solid tissues, such as the liver and kidney, the first step is to prepare cylindrical cores (normally 8 or 10 mm in diameter) with a hand or preferably a motor-driven tissue coring tool. The tissue cylinders are then loaded into a suitable tissue slicer and slices of a defined thickness are produced. For liver slices, the optimal thickness has been established to be 200–250 μm , with limits of usable thickness ranging from 150/180 to 300 μm [1–3]. The optimal thickness of kidney slices is also around 200–250 μm . Tissue slice thickness can be estimated by a number of methods including determination of tissue slice weight or protein content, microscopic examination of freshly cut slices, use of a digital micrometer, and the microscopic examination of formalin-fixed tissue slice paraffin sections [1–3,16].

Commercially available tissue slicers include the Krumdieck and the Brendel-Vitron [1–3]. The Krumdieck tissue slicer is fully automated, with the tissue core being brought across a motor-driven oscillating blade that is submerged in a chamber containing a suitable slicing buffer. The buffer is circulated by a pump and the tissue slices are removed from the blade by a gentle flow of buffer into a glass collecting vessel. In contrast, the Brendel-Vitron slicer is cheaper and less mechanically complex than the Krumdieck slicer. However, it is only semiautomated and uses a rotating blade with the slicing buffer being both circulated and oxygenated by a gas supply. Both tissue slicers have certain advantages and a level of technical expertise is required [1–3]. One study has demonstrated that there was little difference between precision-cut rat liver slices produced with Krumdieck and Brendel-Vitron tissue slicers for studies of xenobiotic metabolism and toxicity [17].

With soft tissues, such as the lung and intestines, agarose is used to enable the preparation of tissue cores. For example, rodent lungs can be filled with a warm agarose solution at 37°C, which is then cooled to 4°C before preparing tissue cores and, subsequently, tissue slices as described above for liver slices [1,2,4]. Intestines can also be filled with warm agarose solution and then embedded in agarose in a core-shaped container to obtain solid cores for slicing [4,18,19]. The optimal thickness of intestinal slices is around 200–250 μm , whereas for lung slices the optimal thickness is around 500–700 μm [1–24].

A wide variety of incubation systems have been developed for precision-cut tissue slices [1–5,20]. Generally, the available incubation systems may be divided into two types, namely, surface culture (where the slices are dipped in and out of the culture medium) and submersion culture systems. One much used surface culture system is the dynamic organ culture system where the slices are floated onto a mesh support

(e.g., stainless steel or titanium) of a roller assembly, which is housed in a suitable vial (e.g., a glass scintillation vial) containing culture medium. The vial is then placed on a roller assembly housed in an incubator or is placed in a purpose-built incubator (e.g., a Vitron incubator). It has been shown that tissue slice viability is extended if the slices are placed on a nitrocellulose filter rather than directly on the mesh of the roller assembly [5,21]. Submersion tissue slice culture systems include the use of Erlenmeyer flasks and 6-, 12-, and 24-well tissue culture plates. For multiwell plates, slices can be simply immersed in culture medium or placed on mesh supports. Both the surface culture and submersion culture systems have advantages, and the choice of incubation system may depend on the particular application of tissue slices under investigation [1–5,20,22,23]. A microfluidic biochip system for the perfusion of liver slices has also recently been described [24].

A number of suitable media for tissue slice preparation and culture media for the incubation of tissue slices from both the liver slices and extrahepatic tissues have been described in the literature [1–4]. Culture media are often supplemented with hormones (e.g., insulin and a glucocorticoid) and bacterial and antifungal agents, the latter being essential to prevent microbial contamination during prolonged incubations. Tissue slices can be incubated under air or gas phases with a higher oxygen concentration, ranging from 40% to 95% [1–4].

15.5 INDUCTION OF PHASE I ENZYME SYSTEMS BY XENOBIOTICS IN PRECISION-CUT TISSUE SLICES

Developments in precision-cut tissue slice preparation and incubation techniques have permitted the culture of slices for several days, which is long enough for their use in xenobiotic-metabolizing enzyme induction studies [1–5,20]. As they contain all the cell types present in a tissue, precision-cut tissue slices can be used to study the effects of drugs and other chemicals on all the xenobiotic-metabolizing enzymes present in that tissue. The most important phase I xenobiotic-metabolizing enzymes comprise members of the CYP superfamily [7–12], whereas phase II enzymes include UGT, sulfotransferase, and GST forms (Section 15.6). This section considers the induction of CYP forms in liver and extrahepatic slices from animals and humans.

Most CYP forms are induced by receptor-mediated mechanisms, leading to an increase in gene transcription [8,10–12]. Important receptors involved in the induction of CYP1A, CYP2B, CYP3A, and CYP4A forms comprise, respectively, the aryl hydrocarbon receptor (AhR), the constitutive androstane receptor (CAR), the pregnane X receptor (PXR), and the peroxisome proliferator-activated receptor alpha (PPAR α). These and other receptors are present in precision-cut tissue slices, thus permitting cultured slices from the liver and other tissues to be used in CYP form induction studies.

The induction of CYP forms in precision-cut tissue slices can be evaluated by monitoring CYP-dependent EAs, CYP mRNA levels, or CYP protein levels. CYP EAs can be determined either directly by adding the substrate to the culture medium or alternatively by removing the slices and preparing whole homogenate and/or subcellular fractions (e.g., postmitochondrial supernatant, microsomes) [25–34]. As xenobiotics and their metabolites may be retained in liver slices if the CYP substrate is added to the culture medium, some workers homogenize the slices in the incubation medium

and then analyze the slice/medium homogenate. However, for some substrates only the incubation medium needs to be analyzed. Because phase II enzymes will also participate in incubations with intact slices, it may be necessary to treat the slice/medium homogenate or medium with a β -glucuronidase/sulfatase preparation in order to quantify the total (i.e., free and conjugated) CYP metabolite(s) produced [23,35]. One study reported that the induction of CYP-dependent enzymes by β -naphthoflavone (BNF) and dexamethasone (DEX) could be detected in both intact liver slices and liver slice homogenates [36]. CYP mRNA levels are best determined by real-time quantitative reverse transcription-polymerase chain reaction (RT-PCR) methodology (e.g., TaqMan®), although other less quantitative procedures have also been employed [27,29,34,37–53]. To normalise for RNA loading, levels of CYP mRNAs are often expressed as a ratio to a suitable control mRNA such as albumin, β -actin, or 18S rRNA. Several studies have examined the effects of xenobiotics on CYP proteins by preparing microsomal fractions and performing Western immunoblotting of selected CYP forms [25,31–34,37,52–60]. CYP proteins may also be determined by enzyme-linked immunosorbant assay (ELISA) procedures [27].

As with other *in vitro* systems, it is important to evaluate a range of xenobiotic concentrations and incubation times in order to ascertain whether the xenobiotic under investigation is an inducer of CYP forms in cultured precision-cut tissue slices. To determine the effects on CYP form mRNAs, only short incubation times may be required (e.g., 3–24 h), whereas to determine the effects on CYP EAs and proteins, longer incubation times (e.g., 24–72 h) may be necessary. In addition, it is imperative to ensure that the chosen concentrations of the xenobiotic studied are not toxic to the tissue slices. Suitable markers of tissue slice viability include leakage of potassium and enzymes (e.g., alanine aminotransferase, lactate dehydrogenase (LDH)), inhibition of protein synthesis, and levels of ATP and reduced glutathione [1–4].

Like hepatocytes [20], levels of CYP forms decline in cultured precision-cut rodent and human liver slices. For example, compared to freshly cut slices levels of CYP1A, CYP2B, CYP2C, CYP2D, CYP2E, CYP3A, and CYP3A4 forms and associated EAs have been shown to decline with time in cultured rat liver slices [25,32,54]. While levels of CYP forms also decline in human liver slices [30,33,34,51,54,55,57], one study demonstrated a differential loss with some CYP forms (e.g., CYP2D6, CYP4A11) being relatively stable over a 72-h culture period, whereas other CYP forms (e.g., CYP1A2, CYP2C19) exhibited a more rapid loss [33]. However, the decline in CYP forms in cultured liver slices does not preclude the use of liver slices as an *in vitro* model system to screen xenobiotics for induction of CYP forms. Indeed, a wide range of chemicals have been shown to induce CYP forms in cultured precision-cut liver slices from animals and humans. Such chemicals include drugs, environmental contaminants, and phytochemicals. Thus, like hepatocytes cultured liver slices can be employed as a model system to assess the potential of NCEs to induce hepatic CYP forms.

15.5.1 Studies in Liver Slices from Animal Species

The majority of studies conducted in animal species have been performed with precision-cut slices prepared from rat liver. Some examples of CYP induction studies in cultured rat liver slices are shown in Table 15.1. The induction of CYP1A, CYP2B, CYP3A, CYP4A, and other subfamily forms have been studied by determination of CYP EAs (intact slices and slice homogenates/subcellular fractions), protein (normally

^aInducers used were: ARO, Aroclor 1254; BNF, β -naphthoflavone; BP, benzo(*a*)pyrene; BUD, budesonide; CARB, carbamazepine; CIP, ciprofibrate; CLOT, clotrimazole; DEX, dexamethasone; DIM, 3,3'-diindolylmethane; 7EC, 7-ethoxycoumarin; ERUC, erucin; 3ICN, indole-3-acetonitrile; ISN, isoniazid; MCP, methylclofenapate; 4Me7EC, 4-methyl-7-ethoxycoumarin; PB, phenobarbital; PCHs, polycyclic hydrocarbons; PCN, pregnenolone-16 α -carbonitrile; SULF, sulforaphane; TCDD, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin; WY, Wy-14,643.

^bEndpoints studied were determination of CYP enzyme activities (EAs), protein levels (e.g., Western immunoblotting), and mRNA levels.

by Western immunoblotting), and mRNA levels. Table 15.1 lists either the CYP subfamily studied or the particular CYP form examined if this was identified (e.g., by mRNA determination or Western immunoblotting).

A number of studies have established that CYP1A forms are inducible in cultured liver slices following treatment with agents such as Aroclor 1254 (ARO) (a polychlorinated biphenyl mixture), BNF, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD),

polycyclic aromatic hydrocarbons (PCHs) including benzo(a)pyrene (BP) and phytochemicals including 3,3'-diindolylmethane (DIM), erucin (ERUC), and sulforaphane (SULF). Some studies [48,52,53] have also examined effects on CYP1B1 as, such as CYP1A1 and CYP1A2, this CYP form is also involved in the metabolic activation of carcinogens including PCHs and heterocyclic amines (cooked food mutagens) [8]. In one study, CYP induction by PCHs was shown to correlate with the potency of the compounds studied to bind to the AhR receptor [53]. Correlations were also observed between the molecular size of the PCHs studied and the induction in rat liver slices of CYP1A-dependent EA, CYP1A1 mRNA levels, and CYP1B1 mRNA levels. The induction of CYP forms by BP in cultured rat liver slices has been shown to be associated with increased levels of BP-DNA adducts [67].

The induction of CYP2B and CYP3A forms in cultured rat liver slices has been demonstrated in studies emanating from a number of laboratories. For example, the induction of CYP2B forms has been demonstrated after exposure of the slices to phenobarbital (phenobarbitone, PB), whereas DEX and/or pregnenolone-16 α -carbonitrile (PCN)-induced CYP3A forms [25,41,42,45–47,54,62–66]. Because of the high degree of similarity between CAR and PXR, a number of inducers function as activators of both nuclear receptors [10–12]. Thus, in some studies, in cultured rat liver slices, PB has been shown to induce CYP3A forms in addition to CYP2B forms, whereas DEX- and/or PCN-induced CYP2B forms as well as CYP3A forms [46,54,63,65]. In one study, a range of NCEs were shown to have variable effects on CYP2B1/2 (i.e., CYP2B1 and CYP2B2) and CYP3A1 mRNA levels in cultured rat liver slices [47]. Moreover, good correlations were observed between the potency of the NCEs to induce CYP2B1/2 and CYP3A1 mRNA levels in liver slices *in vitro* and the potency of these NCEs to induce CYP2B (by EA determination) and CYP3A (by Western immunoblotting) forms after *in vivo* treatment (oral administration to rats for eight days), thus highlighting the usefulness and validity of utilising precision-cut tissue slices to evaluate the potential of a xenobiotic to induce the CYP enzymes. In another study utilizing a series of structurally diverse compounds, a correlation was observed between the induction of CYP3A mRNA levels in cultured rat liver slices and the effects of the compounds in a rat PXR reporter gene assay [68].

While CYP1A, CYP2B, CYP2C, and CYP3A forms are primarily involved in the metabolism of drugs and other xenobiotics [7,8], the CYP4A subfamily forms are involved in the metabolism of endogenous chemical such as fatty acids. CYP4A forms are inducible in rodent liver and this is associated with hepatic peroxisome proliferation [10,12]. The induction of CYP4A forms has also been demonstrated in cultured rat liver slices [43,46,54]. In keeping with known *in vivo* effects, peroxisome proliferators have also been shown to induce peroxisomal fatty acid oxidizing EAs and, by ultrastructural examination, to increase numbers of peroxisomes in cultured rat liver slices [69].

One advantage of the precision-cut tissue slice technique is its ready application to studies of species-, tissue-, sex-, strain-, and age-related differences. In a study of age-related differences, using liver slices from young, adult, and old rats (aged 3, 9 and 24 months, respectively), a decrease in total CYP content and a loss of CYP3A inducibility by DEX were observed in old rats [62]. The treatment of liver slices from one-day-old rats with BNF, PB, DEX, and PCN was shown to result in the induction of CYP1A, CYP2B, CYP2C, and CYP3A marker EAs [63]. In a similar study, the effects of BNF, PB, DEX, and PCN on CYP-dependent activities in liver slices from 1-day-, 40-day-, and 1-year-old rats were investigated [65]. Overall, CYP EAs were

somewhat lower in liver slices from one-year-old rats, whereas CYP inducibility was more pronounced in younger rats.

As tissue morphology is retained in precision-cut tissue slices, the cell-specific and zonal effects of xenobiotics on CYP forms can be investigated. By employing immunocytochemical techniques, a number of studies have investigated the effect of xenobiotics on induction of CYP forms in different regions of the liver lobule. The majority of these studies have focussed on CYP1A forms. In untreated rat liver slices cultured for 24 h, CYP1A1 protein immunostaining was not detected but was detected after BNF treatment [70]. A centrilobular induction of CYP1A1 protein immunostaining was reported in rat liver slices after treatment for 24 h with BP [39] and for 24 h with TCDD followed by 72 h culture in control medium [31]. In another study, CYP1A1 protein immunostaining was not detected in liver slices cultured for 24 h in control medium, but following BP treatment CYP1A1 protein immunostaining was observed throughout the liver slice [48]. Furthermore, a low level of CYP1B1 protein immunostaining was observed in both control and BP treated liver slices. The effect of BNF, PB, DEX, and PCN on CYP1A1, CYP2B1, and CYP3A2 protein expression was assessed in liver slices from neonatal and adult rats [63,71]. In freshly cut slices from adult rats, only weak CYP1A1 protein immunostaining was observed, whereas strong CYP2B1 and CYP3A2 protein immunostaining was detected mainly in centrilobular and midzonal areas of the liver lobule [71]. After 24 h treatment with BNF, increased CYP1A1 and CYP2B1 protein immunostaining was observed, whereas PB increased CYP2B1 and CYP3A2 protein expression and DEX increased CYP3A2 protein expression. Similar results were obtained in studies with one-day-old rats except that an increase in CYP3A2 protein immunostaining was also observed with PCN [63].

Fluorescence confocal laser cytometry has also been used to investigate zonal differences in CYP form induction in liver slices from untreated (control) and BNF-treated rats [72]. An induction of 7-ethoxyresorufin *O*-deethylase (a marker of CYP1A induction) was observed in centrilobular hepatocytes of liver slices from BNF-treated rats, whereas no induction was observed with fluorescent substrates of CYP2B forms.

Compared with the rat, fewer studies have been performed using precision-cut liver slices from the mouse. However, as would be expected CYP form induction can be readily demonstrated in this species. CYP1A-dependent EA was induced in mouse liver slices by BNF and TCDD, with PB inducing CYP2A- and CYP3A-dependent EAs [28]. The treatment of mouse liver slices with BNF has also been reported to induce CYP1A1 and CYP1A2 mRNA levels, with CYP2B10 mRNA levels being induced by BNF, PB, and DEX, and CYP3A11 mRNA levels by DEX [49]. The induction of CYP3A12 and CYP3A26 mRNA levels by various compounds in cultured precision-cut dog liver slices has also been reported [73].

15.5.2 Studies in Human Liver Slices

Some examples of CYP induction studies in cultured human liver slices are shown in Table 15.2. The induction of CYP forms in a number of subfamilies has been investigated following treatment with drugs, environmental contaminants, and phytochemicals.

A number of studies have demonstrated the induction of CYP1A1 and/or CYP1A2 in cultured human liver slices following treatment with agents such as ARO, BNF, BP, and other PCHs, TCDD, omeprazole (OMP), DIM, ERUC, SULF, and phenethyl

^bEndpoints studied were determination of CYP enzyme activities (EAs), protein levels (e.g., Western immunoblotting), and mRNA levels.

isothiocyanate (PEITC). CYP1B1 protein levels have also been reported to be induced by the chemopreventive phytochemicals, ERUC and SULF [60].

Apart from CYP1A forms, in keeping with studies in cultured hepatocytes, a number of other human hepatic CYP forms can be induced in cultured liver slices. These CYP forms include CYP2A6, CYP2B6, CYP2C9, CYP2C19, CYP3A4, and CYP3A5 [34,51,55,59,66,74,75]. Compounds that are known to induce one or more of these CYP forms in human liver slices include chenodeoxycholic acid (CDCA), cyclophosphamide (CP), DEX, PB, PEITC, and RIF. For example, investigations from a number of laboratories have demonstrated that PB and RIF can induce CYP3A4 EA, protein levels, and mRNA levels in cultured precision-cut human liver slices [34,51,55,59,74].

The lobular distribution of CYP2B6 and CYP3A4 induction has been investigated in precision-cut human liver slices [34]. In untreated human liver slices, the distribution of CYP2B6 and CYP3A4 immunostaining was random and centrilobular, respectively. The staining intensities of both CYP2B6 and CYP3A4 proteins were increased following treatment with both PB and CP for 72 h, with no change in the zonal distribution of these two CYP forms being evident.

15.5.3 Studies in Extrahepatic Slices

While the liver is the major site of xenobiotic metabolism in mammals, both phase I and II xenobiotic-metabolizing enzymes are found in many extrahepatic tissues [4,7,8]. Moreover, some extrahepatic xenobiotic-metabolizing enzymes are known to

be inducible. The lung and intestines are important sites of xenobiotic metabolism, as these tissues are the first sites of metabolism of inhaled and orally ingested xenobiotics, respectively. This section focusses on CYP induction studies performed in cultured lung and intestine slices, including investigations performed with human intestine slices.

A number of studies have examined the induction of CYP forms in cultured rat lung, kidney, and intestine slices. As shown in Table 15.3, the treatment of rat lung slices with ARO, BNF, BP and other PCHs, nicotine (NIC), ERUC, and SULF has been shown to induce CYP1A1, and in some instances, the induction of CYP1B1 has also been observed [48,52,53,61,76,77]. Apart from the induction of CYP1A1 and CYP1B1 in cultured rat lung slices, ARO was shown to have a weak effect on CYP2B1/2 mRNA levels [76] and SULF a weak effect on CYP3A2 protein levels [77]. In one study in cultured rat kidney slices, BP was shown to induce CYP1A1 mRNA levels [39].

The effect of xenobiotics on CYP forms in rat and human intestine slices has also been investigated (Table 15.3). Xenobiotic-metabolizing enzymes are not uniformly distributed throughout the intestinal tract, and there can also be regional differences in the effects of CYP inducers [18,19,66,78]. The treatment of rat small intestine slices with BNF, indirubin (IR), and 20-methylcholanthrene (20MC) and colon slices with BNF and 20MC has been shown to induce a CYP1A marker EA [18,78]. Following treatment with DEX, a CYP3A marker EA was increased in cultured rat small intestine slices but not in colon slices [78]. Treatment with PB increased CYP3A9 mRNA levels in both small intestinal and colon slices, and treatment with both PB and DEX increased CYP2B15 and CYP3A9 mRNA levels in colon slices. In another study, the effect of xenobiotics on CYP3A1, CYP3A2, and CYP3A9 mRNA levels in cultured rat jejunum, ileum and colon slices was examined [66]. Treatment with $1\alpha,25$ -dihydroxyvitamin D₃ ($1,25(\text{OH})_2\text{D}_3$)-induced CYP3A1 mRNA levels in cultured rat jejunum, ileum, and colon slices and CYP3A2 mRNA levels in ileum slices. CYP3A1 mRNA levels were increased in rat ileum slices by CDCA, DEX, and PCN, whereas CYP3A9 mRNA levels were increased in jejunum and ileum slices by BUD, DEX, and PCN, with the former two also increasing CYP3A9 mRNA levels in colon slices.

Treatment with BNF increased CYP1A1 mRNA levels in both human proximal jejunum and colon slices [19]. In addition, both PB- and RIF-induced CYP2B6 and CYP3A4 mRNA levels, and DEX-induced CYP3A4 mRNA levels in human proximal jejunum slices. Significant increases in CYP1A (by BNF) and CYP3A (by PB and RIF) marker EAs were also observed in cultured human proximal jejunum slices. While some increases in CYP2B6 (by PB) and CYP3A4 (by RIF) mRNA levels were observed in human colon slices, these effects were not statistically significant. In another study, significant increases in CYP3A4 mRNA were observed in human ileum slices after treatment with BUD, DEX, and $1\alpha,25(\text{OH})_2\text{D}_3$ [66].

15.6 INDUCTION OF PHASE II ENZYME SYSTEMS BY XENOBIOTICS IN PRECISION-CUT TISSUE SLICES

Phase II enzyme systems are closely linked to the deactivation and detoxication of xenobiotics. Conjugation reactions with endogenous substrates, such as sulfate, D-glucuronic acid, glutathione, and certain amino acids, yield highly hydrophilic, readily excretable metabolites [79], although functional groups may also be methylated or acetylated to produce less hydrophilic compounds. Thus induction of these enzyme systems will impact on the metabolic fate and biological activity of chemicals. Toxicologically, a most important enzyme system is the GSTs, which catalyze one of the most important pathways of metabolism that allows the cell to defend itself from chemical insult. It utilizes the nucleophilic tripeptide glutathione, possessing a nucleophilic sulphur atom, to detoxify reactive electrophiles. Indeed, dietary phytochemicals considered to be potential anticarcinogens, such as isothiocyanates, indoles, and curcumin, owe their chemopreventive activity largely to their ability to stimulate conjugation of chemical carcinogens, or of their genotoxic metabolites, with glutathione.

On culturing, phase II activities in precision-cut tissue slices decline, but these enzyme systems appear to be more robust and are better maintained compared with CYP forms [23]. Substantial phase II activity remained in rat liver slices after a 24 h incubation and, in some cases, significant activity was retained even after a 72 h

incubation; for example, the specific activity of UGT, monitored using 2-aminophenol as substrate, did not change significantly following a 24 h incubation, and only a modest loss of activity was noted after 72 h [23]. In concordance, glucuronidation reactions, measured using *p*-nitrophenol, 4-methylumbelliferone, and 4-hydroxybiphenyl as substrates, were more stable than CYP enzymes in rat slices [80,81]. Similarly in human liver slices, form-specific changes were noted when CYP protein levels were determined [33], but glucuronidation of 7-hydroxycoumarin was well maintained [30]. Such observations imply that not only the functional integrity of the enzymes is maintained but also that the slices are capable of synthesizing the necessary cosubstrates for conjugation, such as UDP-glucuronic acid.

The regulation of phase II enzymes by xenobiotics has been the subject of numerous publications, studies being conducted largely *ex vivo* in many animal species, and *in vitro* using systems, such as freshly isolated hepatocytes and cultured cells. It is now established that phase II enzymes are also inducible, in particular, the UGTs, GSTs, and quinone reductase. However, it is evident that phase II enzymes are far less inducible compared with CYP forms, and this is also displayed in slices. Most of the studies conducted in precision-cut tissue slices focussed on the liver, but there is sufficient experimental evidence that induction can be achieved in other tissues. As in the case of CYP forms, two approaches may be used to determine induction of phase II enzymes in precision-cut tissue slices. The first involves incubating slices for a defined period of time, removing the slices, and incubating them once again in fresh medium supplemented with a substrate extensively metabolized by conjugation, the most frequently used being 7-hydroxycoumarin, which is readily conjugated with sulfate or D-glucuronic acid. Alternatively, following incubation of tissue slices with the potential inducing agent, the slices are harvested and subsequently homogenized and subcellular fractions (e.g., microsomes and cytosol) are prepared by differential centrifugation. This second approach is particularly useful when information is required for the modulation of individual forms of the enzyme of interest or for mechanistic studies. Once again, changes in enzyme expression can be determined at the activity level, protein level by immunoblotting, and mRNA by using techniques such as RT-PCR.

15.6.1 Studies in Liver Slices from Animal Species

In order to be able to detect and quantify the inductive potential of xenobiotics, incubation conditions must be first optimised to ensure that maximum induction is attained. One of the most critical factors is the length of incubation time of the tissue slice with the inducing agent. Of course, this will also depend on the biomarker employed to assess the inductive effect, such as mRNA levels or EA. Using the polycyclic aromatic hydrocarbon BP as the model inducing agent, it was revealed that maximum induction of GST activity, determined using 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole as the substrate that is preferentially metabolized by GST α [82], was attained after 24 h incubation and was accompanied by a rise in the enzyme protein levels; no significant change in activity was detected at the earlier time points studied [52]. At the mRNA level, however, an increase was clearly evident as early as 4 h, this being the earliest time point investigated. A similar picture emerged when epoxide hydrolase, monitored using benzo[*a*]pyrene 4,5-oxide, was the investigated enzyme [52]. At the mRNA level, exposure to PB doubled UGT mRNA levels (UGT2B12) in rat slices, but the increase was seen only after incubation of 24 h but not at 2 or 6 h [81].

The next issue that merits discussion is the choice of concentrations of the potential inducing agent; a major attribute of the precision-cut system is that it allows the facile use of a range of concentrations to be investigated. Of course, the chosen range should reflect the concentrations of relevance to human, for example, total plasma, or tissue when available, concentrations following therapeutic intake of a medicinal drug, exposure to an environmental contaminant, or dietary intake of a phytochemical. An initial study should be undertaken in all cases to ensure that the chosen concentrations do not compromise the viability of tissue slices.

Studies employing a number of diverse inducing agents indicated that the upregulation of phase II enzyme systems is concentration dependent. When rat liver slices were incubated with a range of concentrations of BP and, subsequently, the slices were used to assess epoxide hydrolase activity using benzo[*a*]pyrene 4,5-oxide as substrate, a significant increase in activity was seen only at the 10 μ M concentration, and declined at higher concentrations [52]. Increases at the enzyme protein level were detectable at lower concentrations, and when mRNA levels were determined, a significant rise was also observed at relatively much lower doses (0.75 μ M); in both cases maximum elevation occurred at the 10 μ M concentration. Similarly, other PCHs capable of upregulating this enzyme caused a maximal response, either at the activity or protein levels, at about 5–10 μ M, with the response declining at higher concentrations; at the mRNA level, once again increases were evident at much lower concentrations (0.10–0.75 μ M) [83]. When GST activity, determined using 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole as substrate, was monitored, a similar picture was observed following incubation of BP with rat liver slices, in that maximal rise in activity and protein levels was attained at about 10 μ M; in this case, a rise in mRNA levels was evident even at 0.1 μ M. The PCHs dibenzo[*a, h*]anthracene and benzo[*b*]fluoranthene also achieved maximal induction of activity and enzyme protein levels at concentrations of 5–10 μ M with increases in mRNA levels being manifested at much lower concentrations [84].

The value of slices for evaluating the upregulation of phase II enzymes can be illustrated by the use of isothiocyanates, a major class of chemopreventive phytochemicals present in cruciferous vegetables, whose mechanism of action involves detoxification of the reactive intermediates of carcinogenic chemicals [85]. Three such isothiocyanates, namely, ERUC, SULF, and PEITC, upregulated GSTs as well as quinone reductase (a phase II enzyme system that detoxifies quinones) in hepatic precision-cut rat liver slices [86,87].

15.6.2 Studies in Human Liver Slices

Available literature on the induction of phase II enzyme systems in human tissues is limited and largely confined to the liver. Following a 24 h incubation, four PCHs, namely, BP, dibenzo[*a, h*]anthracene, fluoranthene, and benzo[*b*]fluoranthene significantly elevated, in a concentration-dependent manner, epoxide hydrolase activity determined using benzo[*a*]pyrene 4,5-oxide as substrate; parallel increases in enzyme protein levels were also observed [83]. GST activity and expression, on the other hand, were elevated only by benzo[*b*]fluoranthene [84]. At the mRNA level, UGT1A1 and UGT1A6 were upregulated after a 24 h incubation with BNF, whereas when RIF or PB was used as the inducing agent, not all livers responded [74].

Incubation of precision-cut human intestine slices with BNF for 24 h increased UGT1A6 mRNA levels, but in colon slices, there was a very marked variability that

precluded attainment of statistical significance. Similarly, RIF increased mRNA levels in the intestine, but there was a wide variation in the colon. Incubation with quercetin led to a rise in UGT1A6 mRNA levels in the small intestine; a similar increase was seen in the colon but only based on a single human sample [19].

In studies aimed to establish the effect of isothiocyanates on GSTs and quinone reductase, upregulation of these enzymes being considered as an important mechanism of their chemopreventive activity, precision-cut liver slices from human donors were exposed to ERUC, SULF, and PEITC for 24 h [86,87]. In general, marked differences in response were noted illustrating that there are very pronounced differences in the response of human liver to isothiocyanates, raising the possibility that the chemopreventive effect of isothiocyanates may not be manifested in all individuals.

15.6.3 Studies in Extrahepatic Slices

The decline of phase II EAs following culture of precision-cut slices is not confined to the liver. In precision-cut rat lung slices, the glucuronidation of 1-naphthol and sulfation of 2-naphthol were very well maintained over a 72 h incubation period, whereas 50% of GST activity was retained; conversely, under the same conditions, CYP forms were not as successfully maintained [88].

When BP was incubated with precision-cut rat lung slices, a rise in epoxide hydrolase activity was noted only after a 24 h incubation, but an increase in enzyme protein could be observed after an 8 h incubation, although maximal induction necessitated a 24 h incubation [52]. When precision-cut rat small intestine slices were incubated with *tert*-butylhydroquinone, an increase in the glucuronidation of 7-hydroxycoumarin was observed after 24 h but not 5 h [78]. Collectively, these studies demonstrate that the complex signaling systems that regulate the induction of phase II enzymes remain intact and functioning even after a 24 h incubation. Clearly, the length of incubation time required to achieve maximal induction of phase II enzymes may be dictated by the nature of the tissue as well as the enzyme under investigation.

Surprisingly, in precision-cut lung slices exposed to BP, epoxide hydrolase activity was elevated only at 1 μ M, that is, a far lower concentration compared with liver, and this was also evident in the case of other PCHs [52,83]. Whether this difference in concentration reflects the higher metabolic breakdown of BP in the liver compared with lung, thus leading to a lower effective concentration of the inducing agent remains to be established. When precision-cut rat lung slices were incubated with ERUC and SULF, both isothiocyanates elevated quinone reductase and GST activities [77]. In slices prepared from rat small intestine and colon, PB, at a concentration of 4 mM but not 2 mM, enhanced glucuronidation, but not sulfation, of 7-hydroxycoumarin. At a concentration of 8 mM, glucuronidation was markedly impaired; similarly, sulfation decreased, and these effects were paralleled by a drop in viability as exemplified by lower intracellular ATP levels [78]. These studies help illustrate the importance of studying a range of concentrations and ensuring that these do not influence adversely slice viability.

15.7 CRYOPRESERVATION OF PRECISION-CUT TISSUE SLICES

When the validity of the precision-cut tissue system was established, it was inevitable that a lot of effort would be devoted into establishing conditions under which slices

could be cryopreserved so that their functional viability is preserved. This is a pivotal issue particularly with respect to human tissue, the supply of which is limited and unpredictable. In cases where human liver is made available but cannot be immediately used in its entirety, slices could be produced and cryopreserved for storage and subsequent use. Similar considerations apply to tissue from large animals such as dogs, monkeys, and food-producing animals. Cryopreservation would allow a comparison of the metabolic profile of a compound of interest to be investigated so that an appropriate surrogate animal can be chosen for toxicological studies. Moreover, successful maintenance of tissue slices through cryopreservation will inevitably lead to a reduction in animal use.

Considerable effort has been expended into defining conditions of cryopreservation that would maintain the functional characteristics of slices as near as possible to what is observed in fresh slices. For slice viability to be conserved, it is essential that the injury to cells that occurs during cooling and thawing processes is minimised. As a result, the objective is to prevent the formation of ice crystals, which are believed to be responsible for cell death following cryopreservation. Surprisingly, however, it appears that liver slices can survive cryopreservation, following rapid freezing, even when ice crystals are formed intracellularly [89], indicating that other factors may be responsible for the loss of viability. Three fundamental procedures have been adopted to achieve successful cryopreservation of tissue slices: (i) computer-controlled slow freezing to allow cellular dehydration by removal of water from the cells, so that ice crystals are produced extracellularly; (ii) rapid, or even ultrarapid freezing, a much simpler procedure that utilizes relatively lower concentrations of cryoprotectants; slices in the medium are placed in cryovials that are directly submerged to liquid nitrogen; and finally, (iii) vitrification, a process that deploys high concentrations of cryoprotectants, which in itself has the potential to cause toxicity, and employs flash freezing; it leads to the formation of amorphous rather than crystalline intracellular ice. A number of studies have been carried out aimed at defining the conditions that achieve the highest slice viability. To assess slice viability, various parameters have been used, including leakage of lactate dehydrogenase, protein synthesis, intracellular levels of potassium and ATP, histological evaluation, and metabolic functionality, the most frequently employed model substrates being testosterone and 7-ethoxycoumarin. This chapter focusses on metabolic viability when such data is available because of its paramount importance in studies of xenobiotic metabolism and toxicity.

All initial work concerned with cryopreservation emanates from the University of Arizona, where the preparation of precision-cut tissue slices was pioneered with the development of the Krumdieck automatic slicer [1,2]. The potential for cryopreservation was shown in studies employing liver slices from human and pig, an anatomically related animal species, using dimethyl sulfoxide (DMSO) as the cryoprotectant and assessing slice viability using intracellular potassium and protein synthesis as biomarkers [90]; the same procedure was also applicable to human kidney slices [91] as well as to other animal species such as dog and monkeys [91,92]. Vitrification by immersing human slices into liquid nitrogen, using 1,2-propanediol as cryoprotectant, was also demonstrated to be feasible in maintaining viable slices [93]. In these studies, the metabolic competence of the slices was evaluated using 7-ethoxycoumarin; the cryopreserved tissue could catalyze both the CYP-mediated oxidative deethylation of the substrate and the subsequent conjugation of the 7-hydroxycoumarin, demonstrating that the slices maintained the integration of phase I and phase II metabolism of

xenobiotics. However, metabolic integrity of human slices could also be achieved by rapid freezing of the slices in cryovials with DMSO serving as cryoprotectant [94]. In these studies, the metabolism of both exogenous, lidocaine and 7-ethoxycoumarin, and endogenous, testosterone, substrates was used to monitor metabolic function; the same metabolites were generated by the cryopreserved slices as with fresh slices, indicating that the metabolic pattern was not modulated as a result of cryopreservation. Better metabolic viability was reported when rat or human slices were frozen sandwiched between aluminum plates than when frozen in cryovials [95]. In a simplification of this method, the slices were frozen sandwiched between standard aluminum foil; the deethylation of 7-ethoxycoumarin was fully maintained in comparison with fresh slices [96].

More detailed studies were undertaken to better define cryopreservation conditions by comparing the freezing/thawing conditions and the importance of the cryopreservation medium. In these studies, it became evident that the critical aspects of the cryopreservation process were the freezing rate and the nature of the cryopreservation medium. On the basis of studies carried out utilizing rat liver slices, it was proposed that rapid freezing and the Williams Medium E, as compared with the University of Wisconsin organ preservation medium, should be applied to all cryopreservation protocols [97,98]. The optimum concentration of DMSO, itself a toxic chemical, has also been investigated [98]; these authors employed three different concentrations of DMSO, namely, 12%, 18%, and 30%, and observed that metabolic functionality, assessed using 7-hydroxycoumarin and testosterone as substrates, was best maintained at a concentration of 18%. Similar studies by other research groups led to the same conclusion [99]. Even after a six-month storage period, metabolic function of cryopreserved rat and human liver slices, determined using testosterone as biomarker, was well retained [100]; sulfation and conjugation of 7-ethoxycoumarin was fully retained in cryopreserved rat liver slices, but in human slices glucuronidation was halved. It has also been reported that the survival of cryopreserved rat slices post thawing could be extended if the slices were cryopreserved in Williams E medium by rapid freezing and using a high concentration of DMSO (30%). In these studies, metabolic competence was monitored using a number of substrates, but the effect was substrate dependent; for example, the glucuronidation of *p*-nitrophenol was only maintained for 2 h after thawing, whereas the glucuronidation of 4-methylumbelliferone was fully maintained for 24 h, implying that stability may depend on the nature of the enzyme monitored [101]. Whether DMSO concentration modulates the levels of enzyme protein and/or cofactor availability remains to be established. The effect of ultrarapid freezing with DMSO as cryoprotectant has also been studied. Once again metabolic function was dependent on the enzyme monitored; the CYP-mediated hydroxylation of midazolam was well maintained, whereas the conjugation of paracetamol (acetaminophen) with sulfate and D-glucuronic acid was markedly impaired [102]. Interestingly, the metabolic viability of slices, assessed by using testosterone and conjugation with glutathione, was inadequate when cryopreservation was controlled using a computer-controlled slow freezing procedure, which is successful in the case of hepatocytes [103]. Finally, as far as slice thickness is concerned, some researchers reported that it had no effect [97], whereas others observed that thin slices were better maintained, possibly as a result of inadequate diffusion of the cryoprotectant in the thick slices to secure uniform cryopreservation [98].

In a study aimed at assessing the viability of individual CYP forms, seven substrates were used to investigate the metabolic function of rat liver slices following cryopreservation; the rate of metabolism of these substrates, as exemplified by intrinsic clearance Cl_{int} , was not influenced by cryopreservation [104] indicating that it is unlikely that individual CYP forms exhibit different sensitivity to cryopreservation. When metabolic viability of liver slices from a number of animal species, including rat, man, and dog, was assessed, the conjugation of 7-hydroxycoumarin was well maintained after cryopreservation by rapid freezing, and testosterone hydroxylation even increased in the rat and mouse [105].

The vast majority of studies concerned with cryopreservation were conducted in liver slices, and it was anticipated that slices from other tissues would display similar behavior. Using a toxicological end point, namely the ammoniagenic effect induced by the antiepileptic drug valproate, it was established that human precision-cut renal cortical slices were very well preserved in comparison with fresh slices; similarly LDH leakage was unaffected but intracellular levels of ATP decreased [106]. In a recent study, the cryopreservation of rat liver and kidney slices by rapid freezing and vitrification was investigated; viability was assessed using intracellular ATP levels and histologically. As expected, liver slices were viable following rapid freezing but, in contrast, kidney slices were susceptible and viability was severely curtailed [107]. Vitrification of liver slices with VS4, a mixture of 1,2-propanediol, formamide, and DMSO, or VS3, a mixture of ethylene glycol, formamide, and DMSO, led to a marked loss in viability despite the fact that no ice was formed. Vitrification of slices from the renal medulla using VS4 was successful in almost completely maintaining viability but was not suitable for slices from the renal cortex. When vitrification was performed using VS3, kidney slices from both the cortex and medulla were well maintained; thus it would appear that kidney slices are more suited to vitrification. It would be informative to assess the metabolic function of the slices under these conditions. Clearly, one cannot extrapolate from one tissue to another even if they originate from the same animal species.

The ability of cryopreserved tissue slices to respond to inducing agents, that is, the viability of the enzyme synthesis apparatus, has not received much attention. Although cryopreserved precision-cut human slices could respond to the CYP1 inducer BNF, at least at the mRNA level, the effect was less pronounced compared to fresh slices [108]. Subsequent studies by the same workers revealed that the same agent caused upregulation of CYP1 activity level, assessed using 7-ethoxycoumarin, to the same extent in fresh and cryopreserved slices [101]. Elevation of CYP2B1 and CYP3A1 mRNA levels was also demonstrated, to a similar extent, in both fresh and cryopreserved rat liver slices incubated with PB and PCN, respectively [42]. Clearly, more extensive studies are warranted in this area not only to establish inducibility of CYP forms and other xenobiotic-metabolizing enzymes in cryopreserved slice but also to ascertain whether CYP-form-specific differences exist. Inducibility of phase II enzyme systems in cryopreserved slices has not been examined. Moreover, the impact of cryopreservation on the induction process in human liver as well as animal and human extrahepatic tissues are issues that merit further in depth investigation, bearing in mind their potential value.

It is abundantly clear that the success of cryopreservation is dependent on the tissue in question, the animal species from which it derives as well as the nature of the chosen biomarkers for assessing viability. Despite the considerable amount of published

literature in this area, there is no universally agreed and adopted protocol for cryopreservation of liver slices, but rapid freezing in DMSO appears to be effective in most cases.

15.8 CONCLUSIONS

Tissue slices have been used for many decades in biochemical studies, especially in the unraveling of the pathways of carbohydrate metabolism by, among others, Krebs and Warburg. However, because of the difficulty in generating viable slices of uniform thickness, this *in vitro* system was abandoned and was gradually replaced by alternatives, such as primary hepatocytes and cell lines. What reignited interest in this system is the construction, some 30 years ago, by Krumdieck and coworkers of a tissue slicer capable of producing viable thin slices of reproducible thickness, from a number of tissues, which led to the development of the precision-cut tissue slice technique [1–5,20]. The facile generation of tissue slices and the potential applicability of this technique to the use of human tissue attracted the attention of researchers in both academia and industry, and automatic tissue slicers (e.g., Krumdieck, Brendel-Vitron), incubation systems and other equipment were developed and became commercially available. In addition, the published literature describes suitable media for the preparation and culture of precision-cut tissue slices [3,4,20].

Precision-cut slices, as they maintain the cellular architecture of the tissue, function as “mini tissues,” and as such they represent more precisely the *in vivo* situation. A major advantage of the precision-cut tissue slice technique is that once suitable conditions for the preparation of tissue slices from one species (e.g., rat liver slices) have been established in a laboratory, the technique can be readily applied to tissue slices from other species. Moreover, while precision-cut tissue slices can be easily prepared from “solid” tissues (e.g. liver, kidney), procedures have also been established for the preparation of tissue slices from “soft” tissues such as the lung and intestine [1–5,20]. Furthermore, precision-cut slices can be successfully cryopreserved, which is of enormous benefit in human studies, since the availability of fresh human tissue is very limited.

Many studies have been performed with precision-cut liver slices and some studies have compared liver slices with other *in vitro* systems. For example, in a series of investigations with three drugs, namely, almokalant, carbamazepine (CARB), and selegiline, the ability of human liver slices to predict pathways and rates of drug metabolism was compared with human hepatocytes, liver microsomes, and cDNA-expressed CYP forms [109–111]. As both liver slices and hepatocytes contain a full complement of phase I and II xenobiotic-metabolizing enzymes, these systems were superior to liver microsomes and expressed CYP forms in predicting pathways of metabolism. However, human liver slices were less successful than hepatocytes in predicting the intrinsic clearance of the three drugs examined.

A number of studies described in this chapter have established that the induction of xenobiotic-metabolizing enzymes in precision-cut tissue slices concords with *in vivo* observations in animals. All classical established inducers of CYP forms and phase II enzymes have been investigated in tissue slices where they provoked the same response as observed *in vivo*, demonstrating the validity of the system. For human hepatic CYP form induction, cultured hepatocytes are considered to be the “gold standard” and are recommended by the US Food and Drug Administration (FDA) for *in vitro* studies

to assess the potential of a new therapeutic agent to induce hepatic CYP forms in humans [112]. Human hepatocytes have some advantages as, unlike human liver slices, both freshly isolated and cryopreserved human hepatocytes are readily commercially available and human hepatocytes can be cultured in a 96-well plate format, which permits the rapid screening of a large number of chemicals. However, as described in this chapter, precision-cut liver slices can also be employed to screen compounds for their potential to induce CYP forms in human liver.

In conclusion, precision-cut tissue slices are a valuable *in vitro* model system to assess the effects of NCEs on xenobiotic-metabolizing enzymes in the liver and other tissues, from animals and humans. This technique allows the facile and simultaneous comparison of the potential response of different tissues, emanating from one or more animal species, to drugs and other chemicals that would not be possible with other *in vitro* systems, or would have necessitated the use of many animals in *in vivo* studies.

16.1 SUMMARY

For selecting the best drug candidate for development, discovery and development scientists need a profound understanding of the importance of drug solubility and dissolution to identify appropriate formulations/formulation strategies and to estimate formulation impact on drug disposition. This chapter provides detailed information on the importance of solubility and dissolution as rate-limiting steps for oral absorption and reviews formulation approaches to address them. The relevance of solubility and dissolution data for the categorization of compounds according to the Biopharmaceutical Classification System (BCS) and the Biopharmaceutical Drug Disposition Classification System (BDDCS) is highlighted, and the role of maximum absorbable

dose (MAD) as a simple tool for rough estimates of drug absorption is assessed. Also, common elements of solubility and dissolution protocols are presented, and methods addressing equilibrium, apparent, kinetic, and intrinsic solubility, as well as powder and intrinsic dissolution are evaluated. The importance of drug solid state properties for solubility, dissolution, and oral absorption is reviewed, and its early assessment and continuous monitoring in drug batches, assays, and formulations throughout discovery and development is stressed on several occasions in the review as important information to better estimate or reduce development risks. The usefulness of solubility and dissolution data for the identification of appropriate formulations and formulation strategies is discussed. A detailed description of available formulation approaches is provided, including improvement of drug dissolution rate and/or apparent solubility, drug solubilization approaches, and inhibition of drug precipitation. Finally, some general aspects of preclinical formulation strategies and the effect of selected formulations and excipients on bioavailability (BA), pharmacokinetics (PK), and pharmacodynamics (PD) of drugs are briefly discussed. Overall, this review highlights the importance of solubility and dissolution measurements and demonstrates that formulations can, unintentionally or intentionally, have a huge impact on drug disposition and candidate selection.

16.2 INTRODUCTION

Development of new drugs becomes increasingly complex and requires a close, cross-functional cooperation of a multitude of scientific disciplines. Many processes in drug discovery and development are now tightly interfaced and parallelized, and understanding each others terminologies, technologies, needs, and processes is essential and has a huge impact on the speed and efficiency of the drug development process and on the time to market.

After new molecular entities (NMEs) with desired pharmacological properties have been identified in discovery, their physical and chemical properties need to be systematically explored and optimized to rapidly select a “druglike,” “developable” lead compound [1–5]. Ideally, this lead compound combines potency, selectivity, no or acceptable toxicity, and a favorable PK profile into a single molecule. In parallel with the physicochemical characterization of drug candidates, appropriate initial oral and/or parenteral formulations have to be developed to support animal PK, PD, and toxicological studies. Both formulation type and selected pharmaceutical excipients in formulations can markedly affect the absorption, distribution, metabolism, and elimination (ADME) of potential drug candidates, hence, unreflected use of formulations in early PK studies may unintentionally alter the intrinsic PK characteristics of potential drug candidates with sometimes detrimental effects on candidate selection and drug development [6]. Therefore, scientists working in this phase and beyond must have a profound knowledge of not only the drug’s physicochemical properties relevant for development but also a mechanistic and conceptual understanding of the available formulation types and formulation constituents to select appropriate formulations, to interpret PK results correctly, and to actively modulate drug disposition when needed.

Traditionally, medicinal chemists have focused on ligand selectivity and specificity, and during lead optimization, compound properties were chemically modified until the desired PD response, PK profile, metabolic and chemical stability, solubility, and/or

permeability was achieved. Compounds were then handed over to development scientists to test their biopharmaceutical properties and, in case of development liabilities, they were expected to “fix” them, somehow, by formulation approaches. In the past, this often resulted in high attrition rates in later phases or increased development times and costs since compounds turned out to have unfavorable properties for development. Fortunately, this mindset has changed in most research organizations [7]. Development scientists are now becoming involved in drug discovery programs during *in vitro* and *in vivo* optimization itself and can bring in much earlier their thinking and understanding of success factors that are important along the pipeline. This close interaction at the discovery-development interface is expected to address developability criteria early on and to reduce the compound attrition rate during later development.

Despite these changes and efforts for multidimensional optimization of drug candidates, the “new” process does not necessarily yield a “perfect” candidate. Many different properties have to be balanced against each other in one molecule, and optimizing one property may actually compromise another one [5]. Finally, during or after this iterative optimization process, development scientists receive intermediate or final candidate molecules for formulation without an option to further alter the molecular structure according to their formulation needs; an exception is the generation of salts in case of acidic or basic drug molecules. At present development scientists usually first collect available information or generate new data on the most important biopharmaceutical properties of the compound, such as ionization constants, lipophilicity, chemical stability, compatibility, permeability, solubility, and dissolution. These data provide insight into potential compound liabilities and are used to identify suitable formulation options. Unfortunately, developers have limited options to rescue compounds with poor druglike properties by formulation. Metabolic instability and permeability issues typically require additional chemical optimization cycles and can, if at all, only partially be addressed by formulation approaches (Section 16.8). In contrast, developers have a long tradition of handling compounds with dissolution and solubility limitations and a broad range of enabling technologies exist to deliver even high doses.

This review focuses on the importance of dissolution and solubility for the overall *in vivo* performance of drug molecules. The principals and experimental methods for solubility and dissolution measurement are described and both traditional and high throughput (HT) screening (HTS) methods are presented, and their limits highlighted. The importance of dissolution and solubility data for the classification of drugs, the selection of appropriate formulation strategies, and the rational choice of formulation constituents are depicted with a focus on oral drug delivery strategies. Finally, the complex molecular interactions of formulated NMEs in different *in vitro* and *in vivo* surrounding media are discussed. This review does not address rational drug design, identification and optimization of chemical lead structures [8], the pros and cons of HTS strategies [9,10], and the impact of HTS on molecular weight and lipophilicity [11,12] since this has been the subject of several recent and detailed review articles.

16.3 RATE-LIMITING-STEPS IN ORAL DRUG ABSORPTION

Among the different routes of drug administration, the oral route is still the most preferred with respect to patient compliance and for commercial reasons. To achieve high oral absorption, drugs must go into solution, maintain the dissolved state in the

gastrointestinal tract (GIT), and, except for locally acting compounds, must permeate across the intestinal membrane to reach the circulation. Any of these steps may be rate limiting for oral drug absorption.

Membrane permeation is the first barrier for oral drug absorption. Under sink conditions (i.e., drug is immediately removed from the site of absorption and its concentration equals zero inside the membrane), the drug flux (J) (mass/area/time in $\text{mg}/\text{cm}^2/\text{s}$) through the intestinal wall is the effective permeability of the intestinal membrane (P_{eff})(cm/s) and the drug concentration at the intestinal wall (C_W)(mg/cm^3) [13].

$$J = P_{\text{eff}}C_W \quad (16.1)$$

The local mass absorbed per unit time, the absorption rate, depends on the effective surface area (A)(cm^2) and on C_W , which is determined by the available intestinal fluid volume (V)(cm^3) and the amount of drug (M)(mg).

$$dM/dt = P_{\text{eff}}(A/V)M(t) \quad (16.2)$$

The overall absorption rate from the entire intestine is then

$$dM/dt = \int \int_A P_{\text{eff}}C_W dA \quad (16.3)$$

where the double integral is over the entire absorbing surface.

To calculate the total mass of drug M absorbed at time t from the lumen, time- and position-dependent changes in surface area, permeability, and local drug concentration in solution have to be considered [14].

$$M(t) = \int_0^t \int \int_A P_{\text{eff}}C_W dA dt \quad (16.4)$$

This very general equation considers (i) increases in surface area exposed to drug after spreading of fluid in the GIT; (ii) regional differences in P_{eff} caused by differences in the morphology or expression of membrane transporters along the intestinal wall, by formulation effects on membranes, or by ionization of molecules; (iii) drug solubility changes due to variable luminal contents; and (iv) changes in fluid volumes by absorbed or secreted fluids or fluids administered along with the drug.

From Equation 16.4 it can be expected that maximal absorption rate occurs if drug concentration is maintained at saturation concentration (C_S) at the intestinal wall during the whole gastrointestinal (GI) transit, stressing the importance of solubility and dissolution for absorption. Based on this equation, a relatively simple approach to rapidly calculate the MAD (mg) in humans was introduced by Johnson and Swindell [15]

$$\text{MAD} = k_a C_S V t \quad (16.5)$$

where k_a (min^{-1}) is a first-order absorption rate constant and V is the small intestinal water volume (SIWV). The latter may be determined directly, or indirectly, as the slope of the linear relationship between the logarithm of the amount unabsorbed and t , when

TABLE 16.1 Input Parameters for the Calculation of the Maximum Absorbable Dose (MAD) (Eq. 16.6 and 16.7)

	Species			
Parameter		Rat	Dog	Human
Permeability k_a (min^{-1}) P_{eff} (cmsec^{-1} or cmmin^{-1})	High	$>5.02 \times 10^{-5}$ (cmsec^{-1}) (20×10^{-4} cmmin^{-1})	Jejunum/ileum = 0.044/0.11 (min^{-1})	0.0134 (min^{-1})
	Medium	$<4.2 \times 10^{-5}$ (cmsec^{-1})	Jejunum/ileum = 0.0012/0.018 (min^{-1})	0.003 (min^{-1})
	Low			0.0006 (min^{-1})
t (min)		120-180	120	180
V (mL)		3.2 (fasted) 7.8 (fed)	4 (per kg)	250 (500)
A (cm^{-2})		62	4 (per kg)	800
R (cm)		0.2	0.5	1.5
L (cm)		100	255	350

t , small intestinal transit time; V , small intestinal water volume; A , geometric surface area of the small intestine; R , radius of small intestine; L , length of small intestine

Reference and explanation can be found in Section 25.3.

Absorption rate constants k_a and P_{eff} may be converted using Equation 16.6

natural logarithms, that is, logarithms to the base e , are used. k_a can be estimated from *in vivo* P_{eff} by a volume (cm^3) to geometric surface (A) (cm^2) ratio of the intestine as follows:

$$P_{\text{eff}} = k_a(V/A) = k_a(\pi R^2 L / 2\pi RL) = k_a(R/2) \quad (16.6)$$

where R is the radius (1.5 cm) and L is the length (350 cm) of the human small intestine [4] (Table 16.1).

$$\text{MAD} = P_{\text{eff}} C_S 2\pi RLt \quad (16.7)$$

MAD calculations assume a constant permeability along the intestine, and reliable k_a values should be derived from human PK studies. Since such studies are usually not available in early phases, k_a may be derived from the correlations developed between P_{eff} values determined in humans (#640) and in cell lines [16,17] or may even be replaced in the future by parallel artificial membrane permeability assay (PAMPA) values for compounds with pure passive diffusion [18,19]. Gu *et al.* [20] proposed to use for human MAD calculation k_a values of 0.0006 min^{-1} , 0.003 min^{-1} , and 0.0134 min^{-1} for poorly permeable, moderately permeable, and highly permeable compounds [20], respectively; these correspond to Caco-2 P_{eff} of $<20 \text{ nm/s}$, $20\text{--}100 \text{ nm/s}$, and $>100 \text{ nm/s}$, respectively [4]. If validated Caco-2 models are available, human P_{eff} may be calculated for passively diffusing drugs from Caco-2 data; examples are the equations published by Parrott and Lavé [21] [$\log(\text{hum}P_{\text{eff}}) = 0.63 + 0.89 \times \log(\text{Caco-2}P_{\text{eff}})$] and by Sun *et al.* [4] [$\log(\text{hum}P_{\text{eff}}) = 0.7524 \times \log(\text{Caco-2}P_{\text{eff}}) - 0.5441$]. Slightly different k_a values for drug categorization have been suggested by other groups [4,15,22].

A comprehensive summary of measured human P_{eff} values for marketed drugs has been published recently [23]. Detailed descriptions of methods and comparisons of methods [17–19, 23,24] used to determine drug permeability *in vivo* in humans [25,26] and in animals [27,28] or *in vitro* in Caco-2 [29–31], Madin–Darby canine kidney (MDCK) [17,32], or PAMPA model [33,34] are beyond the scope of this review and can be found elsewhere.

The SIWV in man available for dissolving the drug is generally assumed to be approximately 250 mL [15,22,35]; however, this volume might be too conservative for *in vivo* solubility, and for MAD calculations, a volume of 500 mL has been suggested [36–38]. The latter value represents the average SIWV under fasting conditions in humans and could also be a compromise for the 250 mL and 900 mL volumes recommended by FDA guidelines for *in vitro* solubility and dissolution studies, respectively. The mean small intestinal transit time (SITT) (t) in man usually used for MAD calculations is 180 min [4,20]; however, 199 min [39], 240 min [40], 270 min [22] and 360 min [15] have also been reported. The effective available surface area, A , in human proposed by Yu [41] is 800 cm^2 ($11 \text{ cm}^2/\text{kg}$) ($L = 350 \text{ Cm}$; $R = 1.5 \text{ Cm}$); larger value has also been reported [42]. In MAD calculations, C_s is the solubility of the drug in any relevant medium. Since the small intestine is assumed to be the major site of absorption [43], solubility in aqueous buffer at pH 6.5 is used in most cases. However, other pH values have also been reported [20,44] and solubility values from different media such as simulated intestinal fluids (SIF) [45,46] might be more relevant for MAD calculations and for the *in vivo* situation than pure buffer systems [47].

For calculations in other species, MAD input parameters need to be adapted (Table 16.1). In rat, P_{eff} values for high permeability (HP) compounds are $>5.02 \times 10^{-5} \text{ (cm/s)}$ [48] and $20 \times 10^{-4} \text{ (cm/min)}$ [49] and for low permeability (LP) compounds are $<4.2 \times 10^{-5} \text{ Cm/s}$ [48]. In dog, the reported k_a for the medium and HP drugs atenolol (jejunum/ileum $0.0012/0.018 \text{ min}^{-1}$) and propranolol (jejunum/ileum $0.044/0.11 \text{ min}^{-1}$) may be used for guidance [50]. The SIWV volumes proposed are 3.2 mL and 7.8 mL for fasted and fed conditions, respectively [51], and in dog, the water volume administered with the dose, for example, 4 mL/kg , may be used [52]. Average SITT in dog and rat is 120 min [53–55] and 120–150 min [56,57], respectively. The proposed available surface areas for absorption in the small intestine in dog ($L = 255 \text{ Cm}$; $R = 0.5 \text{ Cm}$) [56] and rat ($L = 100 \text{ Cm}$, $R = 0.2 \text{ Cm}$) [49] are $4 \text{ cm}^2/\text{kg}$ [52,58] and 62 cm^2 [56], respectively. As summarized by Varma *et al.* [59], the fraction absorbed (Eq. 16.16) in human correlates well with that in rat and monkey, while dogs show poor correlation and in many instances overpredict human absorption [28]. Human P_{eff} may be calculated from rat P_{eff} using the equation $P_{\text{eff}}(\text{human}) = 11.04 P_{\text{eff}}(\text{rat}) - 0.0003$ [60].

MAD calculations should not be taken as absolute values. Moderate changes in SITT and SIWV do not significantly affect the outcome of a MAD analysis [22]. MAD may be used for rank ordering a series of potential drug candidates [4,44], for predicting food effects [20], for identifying potential reasons of low absorption to trigger additional chemical or formulation activities [22], or for setting certain target properties such as the minimum acceptable solubility for compounds in a project [22,43,61]. For example, an estimated human daily dose of 50 mg of a HP drug ($k_a = 0.03 \text{ min}^{-1}$) will need a minimum solubility of 0.037 mg/mL to be completely absorbed (Eq. 16.5) ($V = 250 \text{ mL}$; $t = 180 \text{ min}$). Limitations of the MAD are that supersaturation, precipitation,

pH-dependent solubility, and solubilization by bile salts/lecithin cannot be adequately modeled.

Even more important, drug dissolution is not considered as a rate-limiting step in MAD calculations. For HP drugs, both drug solubility and dissolution can limit the extent of drug absorption (Eq. 16.4, 16.5, and 16.7). When a dose, M_0 , administered to a SIWV exceeds C_S and drug dissolution rate (= supply) is higher than the uptake rate (= transport across the intestinal barrier), C_W equals C_S and absorption is limited by drug solubility. If dissolution rate is too slow to keep C_S , drug absorption is limited by drug dissolution ($C_W < C_S$). The amount of drug dissolved (m) per unit time (t) is proportional to the difference between C_S (concentration of drug in stagnant layer = equilibrium solubility) and the instantaneous concentration, C at time t , as described by Noyes and Whitney [62].

$$dm/dt = k(C_S - C) \quad (16.8)$$

where k is a constant.

Nernst [63] and Brunner and Tolloczko [64] modified the equation to include other important factors affecting the kinetics of dissolution:

$$dc/dt = DS/Vh(C_S - C) \quad (16.9)$$

where dc/dt is the instantaneous concentration, C at time (t), D the diffusion coefficient (molecular weight dependent, typically $4-8 \times 10^{-6} \text{ cm}^2/\text{s}$ [65]), S the surface area of particle available for dissolution, h the thickness of the stagnant or unstirred water layer (UWL) at the surface of particles, and V the volume of the dissolution medium. Under given experimental conditions, D and h can be regarded as constant and D/h may be replaced by k , also known as *dissolution rate constant* (cm/s). It is assumed that in most cases, a rapid equilibrium is achieved at the solid-liquid interface followed by the rate-controlling diffusion across a thin layer of solution, called *diffusion layer*, into the solution. The latter step is affected by temperature, solution viscosity and composition, degree of agitation, and drug particle size. Depending on the particle size, h may vary (Section 16.5.1.3)

Amidon *et al.* [14,66] have introduced three dimensionless key parameters, D_o , D_n , and A_n , that relate the discussed absorption limiting parameters permeability, dissolution, and solubility, respectively, to the administered dose (M_0).

$$D_o = \frac{M_0/V_0}{C_S} = \text{Dose number} \quad (16.10)$$

$$D_n = \frac{DC_S}{r_0} \frac{4\pi r_0^2}{\frac{4}{3}\pi r_0^3 \rho} t_{\text{res}} = t_{\text{res}} \frac{3DC_S}{r_0^2 \rho} = t_{\text{res}}/t_{\text{Diss}} = \text{Dissolution number} \quad (16.11)$$

$$A_n = \frac{P_{\text{eff}}}{R} t_{\text{res}} = \frac{t_{\text{res}}}{t_{\text{abs}}} = \frac{2P_{\text{eff}}\pi RL}{Q} = \text{Absorption number} \quad (16.12)$$

$$t_{\text{res}} = \frac{\pi R^2 L}{Q} = \text{mean residence time in intestine} \quad (16.13)$$

$$t_{\text{Diss}} = \frac{r_0^2 \rho}{3DC_s} = \text{time required for a particle to dissolve} \quad (16.14)$$

$$\frac{1}{t_{\text{abs}}} = k_{\text{abs}} = \frac{A}{V} P_{\text{eff}} = 2 \frac{P_{\text{eff}}}{R} = \text{the effective absorption rate constant} \quad (16.15)$$

where V_0 is volume available for dissolution, r_0 is the initial particle radius (an average of 25 μm might be used), ρ is the drug density (between 1 and 1.5 for most drugs, an average of 1.3 may be used), Q is the fluid flow rate, and R , L , A , and V are the radius, length, surface area, and volume of the intestinal tube. The dose number, D_o , considers the required dose M_0 (determined from PK and PD studies) and its solubility in the available SIWV, V_0 . If a compound has a high C_s and is administered at low M_0 , D_o is <1 and is not critical. However, if M_0 is high and C_s is low, D_o becomes >1 , and then both the time to completely dissolve drug particles (t_{Diss}) and the time available for absorption (t_{res}) have to be known to estimate, if M_0 can completely go into solution and will be available for absorption. This is expressed by the dissolution number D_n , the ratio between t_{res} and T_{Diss} . If D_n is <1 , not all drug particles will be dissolved during passage through the absorption window in the intestine, and hence drug absorption will be incomplete. Finally, the absorption number, A_n , represents the ratio of the radial absorption rate to the axial convection rate or, in other words, the ratio of the mean residence time of the drug in the intestine to the effective absorption rate constant. It describes the membrane permeation of the drug and provides the information if a drug has a sufficiently high P_{eff} to become completely absorbed during the time it passes its absorption window in the intestine. A_n is species specific since all its variables (R , P_{eff} , L , Q) are species specific. At $A_n = 1$, fraction dose absorbed is 86%, and at $A_n > 1$, complete absorption of a compound is expected, if dissolution and dose do not limit oral absorption [14,66].

In addition to solubility, dissolution, and permeability, drug metabolism is the fourth factor that can significantly limit oral drug BA. Oral BA of a drug should not be mixed up with oral absorption [67]. Oral absorption only refers to the movement of drug across the outer mucosal membrane of the GIT. In contrast, oral BA refers to the availability of the drug at the site of measurement, i.e., general circulation, or to the amount that becomes available at the site of action. Oral BA of a drug (F) can be described as

$$F = f_a x f_g x f_h x \quad (16.16)$$

where f_a , f_g , and f_h are the fractions of intact drug absorbed (f_a) that escape metabolism during passage through the gut wall (f_g) and traverse the liver (f_h) into the systemic circulation [68]. Thus, oral BA can be equal to or less than the fraction absorbed depending on drug metabolism and loss during oral absorption. Before extensive formulation screens are initiated to improve the oral BA of drugs, intestinal and systemic metabolism should always be considered as potential reasons for poor blood levels. This information is extremely important as guidance for the formulation scientist who has a wealth of options to work on compounds with solubility and/or dissolution issues, very few options to rescue compounds with permeability-limited absorption, and almost no tools to handle compounds with metabolic liabilities (Sections 16.6 and 16.8).

Figure 16.1 The Biopharmaceutics Classification System (BCS) after Amidon *et al.* [14] (section 16.4.1). RLS, rate-limiting step; HS/LS, high/low solubility; IVIVC, *in vitro*–*in vivo* correlation; HP/LP, high/low permeability; C_s , saturation concentration; C_w , concentration at gut wall; J , flux across membrane; COG, costs of goods; P_{eff} , membrane permeability; *FDA, EU, WHO, definitions differ.

16.4 BIOPHARMACEUTICAL CLASSIFICATION SYSTEM (BCS) AND BIOPHARMACEUTICAL DRUG DISPOSITION CLASSIFICATION SYSTEM (BDDCS)

The three fundamental parameters, dissolution, solubility, and permeability, which control the rate and extent of oral absorption, have been recognized by Amidon and coworkers, and they proposed a BCS to categorize drugs accordingly [14,66]. The BCS provides a scientific approach to classify drugs on the basis of solubility as related to dose, intestinal permeability, and dissolution properties of an oral immediate-release (IR) dosage form. It categorizes drugs into four classes, on the basis of high solubility (HS)/low solubility (LS) and high/low permeability (HP/LP) (Fig. 16.1). In 2005, Wu and Benet proposed an extended BCS, the BDDCS, which introduced first-pass metabolism in the intestine and/or liver as the fourth factor for the categorization of drugs [69,70].

16.4.1 BCS

The BCS provides a scientific basis for estimating the absorption of drugs and for establishing *in vitro*–*in vivo* correlations (IVIVC) according to Food and Drug Administration (FDA) guidance. The latter is used as a drug development tool to help sponsors

to request a waiver of *in vivo* BA and/or bioequivalence (BE) studies for highly soluble and highly permeable drugs in IR solid oral dosage forms. It sets the relevant criteria under which certain BE studies may be replaced by accurate *in vitro* dissolution studies. The current FDA guidance on biowaivers considers drugs to be highly soluble if the highest clinical dose dissolves in ≤ 250 mL of aqueous medium at pH 1–7.5 at 37°C [71]. It classifies drugs as highly permeable if the extent of absorption in humans is determined to be $>90\%$ of an administered dose. These HS and HP specifications thus correspond to a D_o of <1 (Eq. 16.10) and an A_n of >1 (Eq. 16.12). Since solubility is a static equilibrium parameter, drug dissolution from a solid dosage form is another important factor in the BCS and reflects the dynamic part of absorption. The role of the solubility to dose ratio for the dissolution and GI absorption kinetics of drugs has recently be re-examined by Papadopoulou *et al.* [38] who suggested physiologically based dissolution (D_I) (equal to D_n) and a permeability (P_I) (equal to A_n) indices for categorizing drugs into low ($D_I \leq 3$) and high ($D_I \geq 3$) solubility and low ($P_I \leq 3$) and high ($P_I \geq 3$) permeability drugs, respectively. According to FDA, for rapidly dissolving compounds, $>85\%$ of a dose has to dissolve in less than 30 min in ≤ 900 mL of the recommended pH 1.2, 4.5, and pH 6.5 buffers using USP apparatus 1 or 2. Under these conditions, D_n is <1 (Eq. 16.11), and the administered dose is expected to be completely dissolved and available for absorption. The European Medicines Agency (EMA) [72] and World Health Organization (WHO) [73] conditions differ slightly from FDA recommendations for BCS classification, a comparison of eligibility for BCS-based biowaivers can be found in Tubic-Grozdanis *et al.* [74]. Applications for biowaivers are not feasible if the drug (i) is not stable in GIT, (ii) has a narrow therapeutic range designation, (iii) is absorbed in oral cavity, or (iv) if excipients affect the rate or extent of drug absorption [71].

Based on these definitions, BCS class 1 compounds are drugs that have HS and HP, dissolve to $>85\%$ within 30 min, and are absorbed to $>90\%$ from the small intestine (Fig. 16.1–1). Accordingly, class 1 compounds have $D_o < 1$, $A_n > 1$, and $D_n < 1$ and are well absorbed. Examples of class 1 drugs are digoxin, metoprolol, and caffeine [75]. The dissolution of these drugs is so rapid that differences in the *in vitro* dissolution profile will not affect BA, and hence an IVIVC with dissolution is not expected. After dissolution, class 1 compounds are maintained in solution throughout the intestine and due to their HP (hum $P_{eff} > 2 \times 10^{-4} \text{ cm/s}^1$; (Caco-2: $>10^{-5} \text{ cm/s}^1$ [75]), complete absorption is expected within the absorption window in the intestine. In PK studies, the absolute amount of drug absorbed should increase with increasing doses. Deviations from linearity may result from drug instability in the lumen, presystemic metabolism, the formation of insoluble complexes, or active secretion from the gut wall. The rate-limiting step (RLS) for class 1 compounds is the gastric emptying rate. In the fasted state, emptying is extremely fast for water, with an overall average half gastric emptying time in human of 22 min and 12 min for a 50 mL and 200 mL volume, respectively [76]. More recent studies indicate considerably longer half gastric emptying times of 80 ± 22 min for caloric fluids and 144 ± 55 min for solids [77]. In animal, under fasted conditions, half gastric emptying time of water in rat is 8 min [78] and in dog, similar to human, 35–45 min has been reported for volumes smaller than 100 mL and 10 min for larger volumes [79,80]. Apart from volume, the rate of emptying is influenced in all species by many factors such as energy content, viscosity, density and particle size of gastric contents, temperature, and amount of acid in the duodenum [42,81].

BCS class 2 drugs are highly membrane permeable; however, they have solubility too low to be consistent with complete absorption. An administered dose (M_0) is no longer soluble in ≤ 250 mL of medium pH 1.2–7.5, and hence has $D_o > 1$ (Eq. 16.10). According to Equation 16.7, the MAD is equal to P_{eff} times C_S . Since class 2 drugs have lower C_S , drug absorption is usually slower than for class 1 compounds. Depending on the dissolution behavior of class 2 drugs, C_S may or may not be achieved *in vivo* in the intestine (Fig. 16.1–2). For rapidly dissolving drugs ($D_n > 1$), C_S is achieved and solubility at the gut wall (C_W) is maintained at C_S throughout the absorption window. In this case, drug solubility becomes the rate-limiting factor for oral absorption if the dose administered is higher than the absolute amount that can be absorbed ($M_0 \gg \text{MAD}$). Therefore, an increase in dose will not increase the MAD. It is already at its maximum, and hence an IVIVC is not expected. According to Yu *et al.* [41], typical parameters for solubility-limited class 2 compounds are $t_{\text{Diss}} < 50$ min (micronized drug), hum $P_{\text{eff}} > 2 \times 10^{-4}$ Cm/s (Caco-2 $P_{\text{eff}} > 10^{-5}$ Cm/s [75]), and $\text{MAD} < M_0$. Examples of class 2 drugs are griseofulvin, naproxen, and phenytoin [75]. For compounds with slower dissolution rates ($D_n < 1$), drug removed from the lumen by absorption is not replaced rapidly enough by the dissolving drug, therefore C_W is $< C_S$ and drug absorption is below its theoretical maximum (Eq. 16.7). Here, the RLS for drug absorption is dissolution, and IVIVC can be expected if the *in vitro* dissolution conditions are similar to the *in vivo* dissolution conditions. Gastric emptying time is less important than for class 1 drugs since the drug is exposed for a much longer time to gut wall. Drugs with dissolution-limited absorption typically have $t_{\text{Diss}} > 199$ min (unmicronized drug), hum $P_{\text{eff}} > 2 \times 10^{-4}$ Cm/s (Caco-2 $P_{\text{eff}} > 10^{-5}$ Cm sec⁻¹ [75]), and $\text{MAD} < M_0$. [41]. They show an increase in the absolute amount of drug absorbed with dose since the surface area of the particles available for dissolution increases (Eq. 16.9). Therefore, particle size can also significantly affect the fraction dose absorbed, and in particular, HP drugs dosed at D_n and D_o values around 1 are expected to show highly variable absorption with changes in particle size (Eq. 16.14) [66]. Other factors affecting the kinetics of dissolution are the drugs' diffusion coefficient, the thickness of the diffusion layer, and the volume of dissolution medium (Eq. 16.9). Since they may all be affected by changes in formulation or by the volume, viscosity, pH, and composition (surfactants, complexing agents, etc.) of the medium, the experimental design of dissolution media mimicking the *in vivo* situation for BCS class 2 compounds is challenging (Section 16.5.4).

Drugs in BCS class 3 have HS and LP, and therefore permeability is assumed to be the RLS in absorption (Fig. 21.1-3). Class 3 compounds have $T_{\text{Diss}} < 50$ min (unmicronized drug), hum $P_{\text{eff}} < 2 \times 10^{-4}$ Cm/s (Caco-2 $P_{\text{eff}} < 2 \times 10^{-6}$ Cm/s [75]), and $\text{MAD} < M_0$ [41]; examples are ranitidine and gancyclovir [75]. Class 3 compounds are expected to behave like oral solutions *in vivo* if $>85\%$ of an administered dose will dissolve *in vitro* in 30 min under the condition of the FDA guideline. However, in contrast to class 1 compounds where HP ensures sink conditions *in vivo*, this may not be true for class 3 compounds. The latter have low P_{eff} *in vivo*, and hence dissolved compounds may not be absorbed rapidly enough to create sink conditions *in vivo* for dissolution in the lumen and C_S may become an additional rate-limiting factor (Eq. 16.7). Therefore, more stringent *in vitro* dissolution conditions, $>85\%$ dissolved *in vitro* in 15 min, have been suggested by Yu *et al.* [36] for class 3 to minimize possible dissolution behavior anomalies [82]. The permeability of class 3 compounds often varies along the intestinal tract if drugs show pH-dependent permeability or are substrates

for active uptake or efflux mechanisms [83]. Drugs with an absorption window or a gradient in the permeability along the intestine may exhibit some variability in the rate and extent of absorption [area under the curve (AUC), maximal concentration ($C_{\max}$)], since physiological factors, food, and formulation constituents may influence the transit time through specific regions and/or modulate membrane permeability (Section 16.8) [84]. For class 3 compounds, IVIVC with dissolution is not expected since permeability is the RLS; the absolute amount of drug absorbed increases with dose. Nonetheless, in case of uniform P_{eff} values along the gut, biowaivers might be considered for rapidly dissolving dosage forms that contain common excipients in usual amounts [37,85,86].

If A_n and D_n are low, a drug is considered as a class 4 drug (Fig. 16.1–4). Both solubility and permeability are rate limiting, and compounds have significant oral delivery problems; examples of compounds are furosemide, Taxol, sulfasalazine, and sulpiride [75,85]. Because of their usually LS in the lumen, BCS class 4 drugs are often more susceptible to efflux transporters and gut metabolism than BCS class 3 drugs [59]. Various RLSs may thus contribute to the overall low oral absorption of class 4 compounds. Nonetheless, an IVIVC may still be established for BCS class 4 compounds that exhibit uniformly low P_{eff} along the intestine and slow dissolution rate. If drug dissolution is slow and C_w remains below C_s throughout the intestine, MAD will not be achieved (Eq. 16.5) and, similar to dissolution-limited BCS class 2 compounds, it might be possible to correlate *in vitro* dissolution with *in vivo* absorption.

16.4.2 BDDCS

The criteria for supporting HP of drugs according to FDA are difficult to achieve since they require human PK data, direct permeability measurement, and detailed information about permeability methodology. Because of this regulatory burden, little predictive use has been made out of BCS, in particular for class 2, 3, and 4 compounds. Therefore, in 2005, Wu and Benet [69] proposed a modified version of the BCS, the BDDCS, which categorizes drugs on the basis of their solubility and extent of metabolism. They suggested that if the major route of elimination for a drug is metabolism, it has HP, while if it is excreted unchanged by renal or biliary elimination, permeability is low. It is believed that metabolism represents a surrogate for drug permeability since only drugs that permeate can be metabolized. Metabolism is much easier to access than permeability by *in vitro* incubation studies with hepatocytes and *in vivo* animal and human studies, and thus drugs can be classified without extensive and expensive human permeability studies. Animals are often poor predictors of human metabolism; however, if drugs are not metabolized in animals, this may already be used to assign drugs to BDDCS class 3 or 4. For regulatory issues, Wu and Benet suggested to designate drugs with >90% metabolism as class 1 and 2 compounds [69]. For biowaivers, class 1 compounds should also meet the FDA criteria for rapid dissolution. Overall, the BDDCS predicts if drugs will be highly absorbed; however, it does not predict the extent of absorption [87].

In addition to metabolism, the BDDCS allows predictions of drug disposition and drug–drug interactions [87] (Fig. 16.2). For class 1 compounds, significant transporter effects on absorption are not expected. The HP permits rapid and unaided absorption from the lumen, and even if drugs are substrates for transporters *in vitro*, their HP will not give transporters sufficient access to them or, due to their HS, drug concentration in the lumen will be high enough to saturate them. AUC and oral BA will thus not be

Figure 16.2 The Biopharmaceutics Drug Disposition Classification System (BDDCS) after Wu and Benet [69], and predicted effect (AUC) of inhibition or induction of apical uptake and efflux transporters on oral drug absorption [87] (Section 16.4.2).

influenced by transporters. Class 2 drugs also have HP per se, and hence inhibition or induction of transporters does not affect AUC. However, since LS limits their luminal concentration, saturation of efflux transporters is less likely, and hence inhibition and induction of efflux transporters may increase and decrease AUC, respectively. Drug pumped back into the lumen by efflux transporters will re-enter the enterocytes and thus increase the chance to exposure to metabolizing enzymes in the cell as described previously [88,89]. For class 3 and class 4 compounds, permeability is low and cellular uptake may need transporters, and even for the highly soluble class 3 compounds, intracellular concentration may be too low to saturate efflux transporters. Inhibition of efflux transporters or induction of uptake transporters will increase the AUC of drugs; vice versa, an induction of efflux and inhibition of uptake transporters will decrease it [87,90] (Fig. 16.2). Comparisons show that BDDCS classifies more compounds in class 1 than BCS, and hence more drugs might be eligible for biowaivers [70,90–92]. However, BDDCS has been introduced only recently and the correlation between BCS and BDDCS and their limitations are still under evaluation. Current topics discussed are compounds having HP but low metabolism [92] and how to make use of both BCS and BDDCS for drug classification in the future [87,90,92].

16.4.3 BCS and BDDCS in Drug Discovery and Early Development

BCS and BDDCS are useful tools in discovery and early development to identify RLSs, to rank order compounds, and to communicate potential higher formulation risks. In

later phases, the BCS is used as a regulatory tool to identify IVIVC and to obtain waivers for *in vivo* BA and BE testing according to FDA [93]. Waivers are designed to replace *in vivo* BE studies for IR products by *in vivo* dissolution studies, which can both reduce costs and improve the quality of medicines. Waivers were originally designed only for class 1 drugs; however, extensions to other classes have also been recommended [36,37,94,95].

In discovery, BCS is now also frequently used to identify potential compound liabilities early on and to design appropriate animal and human formulations [96,97]. With the introduction of HTS technologies for the characterization of the physicochemical properties of lead compounds around 1990, a shift in BCS classes is observed. Comparisons of marketed compounds and NMEs performed by several authors revealed a drop in class 1 compounds from 40% to ~20% and an increase in class 2 compounds from 30% to ~60% among the portfolio compounds of major pharmaceutical companies over the past two decades; class 3 and 4 compounds remained in the range of 10–20% [3,7,69,97–99]. This increase in class 2 drugs is presumably the result of the quest for higher binding efficiency, higher potency, and/or targets with properties unfavorable for oral absorption that ultimately led to larger and more lipophilic molecules with overall lower solubility. Lipinski and coworkers have summarized this trend in the famous “Rule of 5,” which indicates that molecules with MW >500, log *P* > 5, > 5 H bond donors (as a sum of NH and OH), and >10 H bond donors (N + O) are less likely to have good oral BA [1]; higher MW also means more rotatable bonds and rings [2]. Such compounds are also more prone to drop out during the development process [11] and to have poor absorption, distribution, metabolism, excretion, and toxicity (ADMET) properties [100].

Decision making based on BCS classification in early phases first requires definition/identification of a drugs’ BCS class on the basis of solubility, dissolution, permeability, and dose information [96,97]. While the first parameter is relatively easy to assess in early phases, the others are less available. Experimental solubility can be determined by traditional shake flask methods or by more compound-saving miniaturized methods. Dissolution testing using standard USP dissolution methods is often not feasible in discovery because of limited compound availability; however, microscale assays have been introduced recently. Particle size measurement may be helpful for dissolution estimation and may be done by simple optical microscopy or by more sophisticated methods such as laser diffraction, centrifugal sedimentation, or scanning electron microscopy (SEM) as reviewed recently [101,102]. A detailed discussion of solubility and dissolution measurements can be found in Sections 16.5.3 and 16.5.4, respectively. As a rule of thumb, dissolution-limited absorption is seldom observed if drug solubility is >0.1 mg/mL [85]. In early phases, drug permeability in humans is not available and permeability estimations for BCS classification need to be derived from established correlations of human absorption values [4] with *in vitro* models (PAMPA [19], Caco-2 [24,32], MDCK [23]), *in situ* studies [27,49], or *in vivo* animal experiments [48]. Also often in this phase the clinical dose is not available and hence *D*_o cannot be calculated accurately. If experimental data are not available, *in silico* tools with different levels of complexity may also be used to predict oral BA [103,104]; however false positives are still possible since large and high quality datasets are often missing and compounds with poor and intermediate absorption are underrepresented in training sets. Commercially available tools for prediction are Stella[®] [105], GastroPlus[™] [106–108], PK-Sim[®] [109] Simcyp[®] [110], and the

TNO integrated software [111]; the pros and cons of absorption modeling have been reviewed in 2009 by Fotaki [112]. In recent studies, provisional BCS classification of marketed drugs was established on the basis of *in silico* calculation of solubility and permeability [91,113]. Here, compounds with a $\log P$ greater than metoprolol ($\log P = 1.72$) were categorized as HP drugs; however carrier-mediated uptake is not considered, hence incorrect classification is possible [92]. Moreover, Shugarts *et al.* [87] recently pointed out that BCS cannot be used for the prediction of drug disposition since the extent of absorption does not correlate with permeability in a number of cases. For example, the BCS class 2 compound talinolol has LS and a high extent of absorption; however, its measured permeability is low. Thus the FDA definition for HP and LP confounds permeability and extent of drug absorption.

In practice, NMEs do not necessarily have to meet BCS class 1 criteria to be developable. Many Class 2 and some class 3 and 4 compounds have also made it to the market. Actually, certain targets may even require properties unfavorable for oral absorption to be highly active [114]. These drugs may still be rescued by administration via a different route, and indeed, a comparison of oral and injectable drugs has shown that the latter tend to have higher molecular weight, more polar groups, lower lipophilicity, and more rotatable bonds than oral drugs [12]. However, it is also clear that the resources to develop drugs increase in the order of BCS class $1 < 2 < 3 = 4$ and that poor physicochemical properties are likely to increase time to market and the attrition rate of drug candidates [12]. Typically, BCS and BDDCS classification is based on experimental data; however, recently, computational models also became available that predicted them reasonably well [91,113,115–117]. These *in silico* tools will hopefully speed up the drug discovery and development process in the future and help to reduce costs. For marketed drugs, a number of provisional classifications have been published [69,91,98,118,119].

16.5 SOLUBILITY AND DISSOLUTION

The previous sections pointed out the importance and the interplay of solubility, dissolution, permeability, and metabolism in combination with the administered dose as potential rate-limiting factors for oral drug delivery. In most companies, a major proportion of new compounds in drug pipelines now tend to fall into BCS class 2 [97], and hence compounds exhibit LS and HP or, according to BDDCS, extensive metabolism (Section 16.4.2). The latter is usually addressed early on by *in vitro* microsomal or cellular assays or by testing in animals, and liabilities identified are corrected by medicinal chemists accordingly by structural modifications, if feasible. Thus for an increasing percentage of drugs, solubility and dissolution become rate-limiting factors for oral absorption and their exact measurement will set the stage for candidate selection and formulation development for compounds that have no permeability issues (BCS class 1 and 2). This section provides an overview of common definitions of different types of solids, solubility, and dissolution and review the experimental methods used to determine them. Several excellent reviews covering solubility [120,121], sparingly soluble ionizable compounds [122], salt formation and selection [123–125], polymorphs [126,127], cocrystals [128], and dissolution [129,130] provide the background for this discussion.

Figure 16.3 Schematic presentation of equilibrium, apparent, and kinetic solubility of drugs. Detailed explanations can be found in Section 16.5.1.1.

16.5.1 Definitions

16.5.1.1 Solubility. Solubility is fundamental in drug absorption, and both PK and PD can be affected by insufficient solubility. However, although solubility is a parameter that is conceptually easy to measure, unclear terminology may cause some misconceptions about solubility as pointed out by Sugano and colleagues [131]. This review basically follows their definitions.

Equilibrium solubility represents the concentration of the solute in its *saturated solution* C_S , where the saturated solution is in a dynamic equilibrium with an excess of undissolved solid compound (Figs. 16.1 and 16.3). As long as temperature, solid concentration, and solid form remain unchanged, the concentration of the solute is constant at equilibrium, since the rate of compound dissolution equals the rate of precipitation. At equilibrium, the dissolved molecule in solution can exist as monomer, dimer, higher self-aggregates, or complexes with larger molecules or be incorporated into micelles [131]. Time course measurements are required to confirm the equilibrium and to exclude transformation of solid into a more stable form. Equilibrium solubility is often regarded as being the “true” solubility; however, measured values can be affected by a multitude of compound properties and experimental artifacts (Table 16.1 in Ref. 120). The general solubility equation (GSE) of Yalkowsky and Banerjee may be used to estimate drug solubility from the octanol/water partition coefficient ($\log P_{OW}$) and

Figure 16.4 Relationship between drug solubility and time required to completely dissolve spherical particles of a given diameter (Section 16.5.1.3).

the melting point (MP) [132].

$$\log S = 0.8 - \log P_{OW} - 0.01(\text{MP} - 25) \quad (16.17)$$

Apparent solubility describes the apparent equilibrium reached after a long incubation time (typically several hours to a day) between drug in solution and a solid (Figs. 16.2 and 16.3). The solid is not necessarily in its most stable form and may be a powder or precipitated solid from for example, a concentrated drug solution in dimethyl sulfoxide (DMSO). Apparent solubility may decrease with time and is distinct from true equilibrium (thermodynamic) solubility, which is reached at infinite equilibrium time.

Kinetic solubility is the solubility measured immediately (minutes to a few hours) after the addition of a concentrated drug stock solution into an aqueous medium (Figs. 16.3 and 16.3). Therefore, kinetic solubility measures an antisolvent precipitation rather than solubility and represents the maximum solubility of the fastest precipitating species of a compound [121]; hence kinetic solubility is often significantly higher than equilibrium solubility. Kinetic solubility is strongly time dependent, and solubility values are not expected to be reproducible between different kinetic experimental setups (Section 16.5.3.1). In particular, precipitation from organic solutions may generate thermodynamically less favorable solid forms that may converted with time to more stable or to the most stable thermodynamic form according to “Ostwald’s Rule of Stages” [133] (Figs. 16.3 and 16.4)

Intrinsic solubility, S_0 , is defined as the solubility of the uncharged form of molecular species (undissociated, neutral) of an ionizable compound. Intrinsic solubility is determined at a pH where the compound does not dissociate.

Other commonly used terms are unbuffered/buffered solubility and unsaturated/supersaturated solutions. *Unbuffered solubility* means the solubility of a saturated solution of the compound in water at the final pH of the solution, and

buffered solubility is the saturated solubility in a pH-buffered system. In *unsaturated solutions*, compound concentration is below C_S . Under certain conditions, *supersaturated solutions* may also form, that is, drug concentration in solution exceeds C_S (Section 16.6.5). Brouwers *et al.* [134] has suggested to use the supersaturation ratio (S) and the supersaturation index (σ) for their characterization.

$$S = \frac{C}{C_S} \quad (16.18)$$

$$\sigma = \frac{C - C_S}{C_S} \quad (16.19)$$

where unsaturated, saturated, and supersaturated solutions have $\sigma < 1$ ($S < 1$), $\sigma = 0$ ($S = 1$), and $\sigma > 0$ ($S > 1$), respectively.

16.5.1.2 Solids. The solids used to determine equilibrium solubility can exist in several different solid states, such as amorphous form, hydrates, polymorphs, and solvates. *Amorphous solids* have no long-range three-dimensional order and are characterized by disordered, short-range arrangement between constituent molecules like in a liquid. Polymorphism in pharmaceuticals, describes the ability of a compound to exist in 2 or more crystalline forms. *Polymorphs* have the same empirical formula; however, they differ in the arrangement and/or conformation of the molecules in the crystal structure and typically have different lattice energies. In contrast, *solvates* have different empirical formulas and contain the substance and water (hydrates) or other solvent molecules in the crystals.

The solution process of a solid in a solvent can roughly be divided into three steps: first, a molecule is freed from the solute, second, a hole is created in the solvent, and third, the hole in the solvent is filled by a free solute molecule [121,127]. This process will continue until the energy required to break a molecule out of a solid matrix equals the energy returned from solvent–solute interactions. Since amorphous solids require less energy to release molecules from solids, they often have higher apparent solubility than crystalline forms. The solubility advantage between amorphous and crystalline form was predicted to be 10- to 1600-fold; however, the actually measured ratios were only in the range of 1.1- to 24-fold [135]. Nonetheless, much higher ratios may be achieved, and an experimental ratio of amorphous to crystalline form of 6000 has recently been reported for cinnarizine [136]. In contrast, the solubility difference among crystal polymorphs seems to be only in the range of 2- to 5-fold [126]. Experimental apparent solubility values higher than for the pure crystalline form may result from undetected amounts of amorphous substance [135]. As a rule of thumb, hydrates have a lower solubility in water and a higher solubility in solvents miscible with water than their corresponding anhydrides [137,138].

Amorphous forms are thermodynamically unstable and may crystallize. Therefore, if solubility studies start with metastable solids, phase transition to more stable forms may occur if the activation energy barrier can be overcome [127]. Real equilibrium solubility is achieved only when the energy of solvents and solute, to interact with themselves, and of solute and solvent, to interact with each other, is balanced. Thermodynamic solubility would then be the solubility of a saturated solution of the compound in equilibrium with the thermodynamically most stable polymorph at a given temperature and time.

16.5.1.3 Dissolution. Solubility represents a static phenomenon. In contrast, dissolution rate describes the speed at which certain solubility is reached. According to the Nernst–Brunner equation (Eq. 16.9), the dissolution rate is directly proportional to the saturation solubility C_S and the surface area S exposed to the dissolution medium and is expressed as the amount of compound liberated per time per area. During the dissolution of particles, the surface area available for dissolution constantly changes. Hixson and Crowell [139] derived an equation from the Noyes–Whitney equation that expresses the rate of dissolution based on the cube root of the weight of the particles [140]. When this model is applied to micronized particles, the change in particle radius with time is given by [127,140]

$$r^2 = r_0^2 - \frac{2DC_S t}{\rho} \quad (16.20)$$

where r is the radius of the particle at time equal to t , r_0 the initial particle radius, D the diffusion coefficient of the molecules dissolving from the particle, C_S the equilibrium solubility of the compound, and ρ the density of the particle (typical values are $D = 5 \times 10^{-6} \text{ cm}^2/\text{sec}$, $\rho = 1.3 \text{ g/mL}$). The equation assumes an aqueous diffusion layer around the particles comparable to or larger than the particle radius. The time required to complete particle dissolution ($r^2 = 0$) (T_{Diss}) may then be approximated from

$$T_{\text{Diss}} = \frac{\rho r_0^2}{2DC_S} \quad (16.21)$$

In Fig. 16.4, the time to complete dissolution is plotted against the particle diameter for four hypothetical compounds with different solubility. The graph shows, as a rule of thumb, that particle size reduction may not be needed for complete dissolution if the particle diameter (in micronmeter) is smaller than the aqueous solubility (in $\mu\text{g/mL}$). Moreover, compounds with $C_S > 0.1 \text{ mg/mL}$ in the pH range 1–8 and with particle diameter $< 50 \mu\text{m}$ are likely to completely dissolve during SITT (180 min), assuming sink conditions ($C \ll C_S$ in Eq. 16.8), spherical particles, and no particle agglomeration due to bad wetting properties [141]; on the contrary, compounds with aqueous solubility $< 0.1 \text{ mg/mL}$ often present dissolution limitations to absorption [142]. For other particle size ranges, different relationships may apply [130,143]. For example, in the small particle regime, experimental data indicate that dissolution time is proportional to the square of the diameter [144]. For dissolution simulation (Eq. 16.20), Sugano *et al.* [131] suggested to set the diffusion layer thickness (h), equal to the radius (r) for particles $< 30 \mu\text{m}$ and to use $h = 30 \mu\text{m}$ for particles with $r > 30 \mu\text{m}$. Reviews of dissolution modeling and comparison of dissolution profiles can be found elsewhere [130,145].

For ionizable compounds, the pH at the surface of the dissolving particles (pH_0) can deviate up to several units from the pH of the bulk solution since dissolving acids will lower and dissolving bases will increase pH_0 (self-buffering) [146–148]. This difference between pH_0 and the pH of the dissolution medium will rise with increasing intrinsic solubility (S_0) of compounds (=higher buffering capacity of compound) and with decreasing buffering capacity of the dissolution medium. The saturation solubility C_S of a compound at a particular pH can be written for monoprotic

compounds as

$$C_S = S_0(10^{\text{pH}-\text{p}K_a} + 1) \quad \text{or} \quad \log C_S = \log S_0 + \log^{\text{pH}-\text{p}K_a} + 1 \quad (16.22)$$

for an acid and as

$$C_S = S_0(10^{\text{p}K_a-\text{pH}} + 1) \quad \text{or} \quad \log C_S = \log S_0 + \log^{\text{p}K_a-\text{pH}} + 1 \quad (16.23)$$

for a base (equations for di- and triprotic molecules can be found in Ref. 149). As can be seen, a decrease (acids) or an increase in pH (bases) will decrease C_S at the surface of particles compared to C_S in the bulk. Therefore, both the use of bulk C_S in Equation 16.9 or of a buffer system in dissolution assays with a capacity above physiological conditions will overestimate the initial dissolution rate of a compound. A practical method to determine pH_0 was established by Serajuddin and Jarowski [150].

Similar to C_S , D is also inversely proportion to t_{Diss} (Eq. 16.21). The Stokes–Einstein equation describes the relationship of the diffusivity to the viscosity of the medium η , the temperature T in Kelvin, the radius of the drug molecule r_M , and the Boltzmann constant k_B

$$D = \frac{k_B T}{6\pi\eta r_M} \quad (16.24)$$

Diffusion through the UWL, also called *UWL permeability* (P_{UWL}), limits the intestinal permeability of highly permeable drugs as well as their diffusion away from the surface of particles during particle dissolution. P_{UWL} can be described by D , the diffusion layer thickness (h) coefficient, and the molecular weight (MW) and may be modeled by Takano *et al.* [52]

$$P_{\text{UWL}} = \frac{D}{h} = \frac{k_B T}{6\pi\eta r_M} = 16 \times 10^{-4} \times \left(\frac{180}{\text{MW}} \right)^{1/3} \quad (16.25)$$

Therefore, changes in compound diffusivity, for example, by an increase in molecular weight by incorporation into micelles or increases in viscosity by food intake, may significantly decrease P_{UWL} and hence the dissolution time of particles.

Since dissolution rate depends on the available surface area, S , direct comparisons of powders with different particle sizes are difficult to perform. Therefore, investigative studies in drug development are done using the *disk intrinsic dissolution rate* (DIDR) technique. Here, compound is compressed in a punch and die and only one planar face of the compressed powder disk is exposed to the dissolution medium. Under these conditions, the surface area exposed to the medium (typically 0.5 cm^2) [151] is regarded as constant and the DIDR is the amount of compound released from a unit area of the solid drug per time (mg/min/cm^2). According to the modified Noyes–Whitney equation (Eq. 16.9), the dissolution rate per unit area (= mass flux) is then directly proportional to C_S , since at the earliest stage, $C \ll C_S$. For good reproducibility, agitation intensity, dissolution volume, and dissolution vessel configuration need to be well controlled. Yu *et al.* [151] found good correlations between DIDR and BCS solubility class membership with 0.1 mg/min/cm as a class boundary unless the dose is extremely high or low or experimental conditions used for DIDR and solubility differ significantly.

Figure 16.5 Quantitative and qualitative considerations for the setup of solubility and dissolution assays in different phases of drug development (Section 16.5.2.1).

16.5.2 Measurement of Solubility and Dissolution

16.5.2.1 Common Elements of Assays. The focus and setup of solubility and dissolution assays changes from discovery to preclinical and clinical development (Fig. 16.5). In discovery, the number of compounds to test is high and only small quantities of compound are available. Solubility assays address kinetic solubility and compound dissolution is usually not tested. The focus is on screening and rapid decision making. For the sake of speed, many important experimental factors such as solid state properties (crystallinity, initial and final polymorphic form, particle size, flowability, chemical stability, etc.) are not controlled, and hence the data quality or confidence into these data is often low and there is a higher risk for selecting compounds with inappropriate properties for development than in later phases [120]. In contrast, in later development phases (Fig. 16.5), compound availability is not an issue. There are usually only one to two compounds remaining that are extensively studied in highly controlled equilibrium solubility and compendial powder and intrinsic dissolution assays. The data generated in late development and clinics are of high quality and are used for regulatory documents. In between, in the preclinical phase, the focus is on candidate selection, and here both speed and quality have to come together. Compound availability may still be an issue, and although only a few compounds are investigated in more depth, some throughput is required to select in a reasonable time appropriate solvents, polymorphic forms, and/or salts for animal and human formulations and for the identification of long-term formulation options [120]. Solubility assays are either short time (<24 h) equilibrium or kinetic/equilibrium hybrid assays, and dissolution is performed with milled or unmilled powders. The initial and final solid state properties of compounds in the assays are also looked at and, compared to discovery, data quality and confidence into data increases and selection risk for the right candidate decreases. Nonetheless, the workflows for solubility and dissolution assays in all phases have a number of key elements in common as shown in Fig. 16.6. Compound and solvent have to be distributed and

Figure 16.6 Key elements of (HT) solubility and dissolution assay workflows (Section 16.5).

mixed, and after an incubation step, depending on the assay, solid and liquid often have to be separated from each other before analysis.

16.5.2.2 Compound Distribution. For the distribution of one solid compound to one or to a few vials, manual distribution using a spatula and a fixed standard four- or five-digit balance for weighing is still the most popular and efficient method. It is rapid, works with a minimum amount of solid, does not need extra calibration of dispensing instruments, and is not prone to cross-contamination. However, if the focus is on medium to high throughput and on one-to-many or many-to-many distributions, appropriate approaches have to be identified that substitute balances and the labor-intensive and time-consuming weighing process. A number of companies offer automated powder dispensing systems, and the different dispensing techniques and associated challenges have been reviewed recently [120,152]. Most of these systems are expensive and designed for the development phase where compound availability is not an issue. In discovery, most compounds are available only in small amounts and significant compound losses cannot be tolerated. Here, different strategies have to be applied. Despite the known challenges in the handling and storage of DMSO stock solutions [3,153–155], DMSO stocks have become a de facto standard for compound distribution in discovery for various assays and are now also used for solubility screening. The compound is either added as DMSO stock directly to solvents or is used as solid starting material after DMSO evaporation of the stock solution under low pressure [120,156] (Section 16.5.3). DMSO may be replaced by other solvents such as acetonitrile [157], MeOH/DME [158], acetone [159], or acetone/EtOH [160]. In all cases, the solid starting material generated by either precipitation or evaporation is not characterized and may differ from the initial solid state properties. Viable, manual alternatives to DMSO stocks that do not change initial solid state properties are

compound distribution in suspension in a nonsolvent [161] and small-scale volumetric dispensing systems, such as the Titan 96 Well Resin Loader™ from Radleys Discovery Technology [162,163], the Biodot handheld DisPo powder dispensing pipettes (<http://www.biodot.com>), and the Gilson MICROMAN® positive displacement pipette-based “PowderPicking” technology [164]; reported lowest target masses delivered are 0.5 mg, 10 mg, 0.1 mg, and 0.5 mg, respectively.

16.5.2.3 Solvent Distribution and Solvent Selection. Solvent distribution is usually straightforward and not considered as a problem. Commercially available solutions for liquid handling range from simple manual pipettes to highly sophisticated, programmable, 96-tip, robotic systems. These systems are often already available in discovery settings and can be used for aqueous solvents without further modification. In contrast, organic solvents or highly viscous solvents are more demanding and may require specialized equipment or adaptation of aspiration/dispensing protocols as discussed recently [120]. A popular, low technology solution for the manual manipulation of more problematic solvents is the Gilson MICROMAN® positive displacement pipette. Another approach is the solvent casting method [159,160,165]. In this approach, the solvent is first mixed with an organic solvent to facilitated distribution and the organic solvent is subsequently removed by evaporation.

For solubility studies, the traditional solvents used in discovery are water and simple buffer systems. However, in particular, for the increasing number of BCS class 2 compounds (Section 16.4.1), solubility in these solvents often underpredicts the oral absorbability of compounds. Therefore, more biorelevant media, such as simulated gastric fluid (SGF), fasted simulated small intestinal fluid (FaSSIF), and fed simulated small intestinal fluid (FeSSIF), are now used already in early phases. These media often increase the apparent solubility of compounds and their dissolution rate, and they seem to provide a better basis for the ranking of compounds and for absorption simulations [40,166,167]. In early- and late-phase development, these media represent a de facto standard; however, the original media [166,167] are constantly developed further to improve their predictive power [168–170]. In the preclinical phase, a large variety of additional solvents is usually tested to generate a “solubility fingerprint” for each compound to support formulation selection and development; examples are solutions of surfactants, cyclodextrins (CD), or cosolvents in water, pure cosolvents and surfactants, medium- and long-chain mono-, di-, and triglycerides, and organic solvents [161]. Solubility values in the latter are required to support salt and polymorph screening, process and analytical chemistry, cleaning validation, and the preparation of solvent-based solid solutions [120,160,171].

For dissolution studies, 0.1 N HCl or Simulated Gastric Fluid USP without enzymes, pH 4.5 buffer, and pH 6.8 buffer are commonly used media for the BCS classification of drugs [71,172]. Other widespread dissolution media are FaSSIF and FeSSIF, which are used for establishing IVIVC and for predicting the oral absorption of BCS class 2 compounds. Dissolution media often contain surfactants, cosolvents, CD, or lipids to dissolve larger fractions of LS compounds in a reasonable time. Such media are used for formulation development, as control tools for manufacturing or for the determination of product stability in quality control and in research and development [173–176]. A decision tree for dissolution method development and for the selection of appropriate dissolution media for different categories of drugs has been proposed by Li *et al.* [177] based on the work from Dressman [178].

16.5.2.4 Mixing of Compound and Solvent. Experimental approaches to efficiently mix compound and solvent have been the focus of a number of reviews over the past years [120,179,180]. Depending on the compound and the solvent tested, mixing can be challenging and the method used may affect the outcome of an experiment. In solubility and powder dissolution studies, particles should be rapidly and homogeneously distributed in solvents to maximize the initial surface area exposed to medium. Continuous intense mixing will also decrease the height (h) of the UWL at the surface of particles, improve their wetting, and avoid particle (re)aggregation. This will ensure a high dissolution rate (Eq. 16.9) and the rapid reaching of saturation solubility. However, the high energy introduced by too extensive stirring or sonication may also induce partial or complete amorphization and result in an overestimation of drug solubility. Higher apparent solubility due to an increased surface area is also expected during stirring where particles may be “milled” between the wall of the incubation vessel and the stir bar, particularly in small scale approaches with high vessel surface to volume ratios [161]. On the contrary, insufficient mixing may lead to reduced particle surface due to bad wetting, aggregation, or floating of particles of LS compounds and incubation time might be too short to reach saturation solubility. These problems might be overcome by adding glass beads to deaggregate particles [179] or surfactants below their critical micelle concentration (CMC) for wetting [181] or small amounts of predissolved compound in an organic solvent to temporarily generate supersaturated solutions. In kinetic solubility studies, too intense shaking [182] or the insertion of stir bars [183] was found to decrease the measured solubility for LS compounds for unknown reasons. Other important factors to control during mixing and incubation are the avoidance of solvent evaporation and of “dead spaces” [161,163]. As pointed out recently, highly viscous solvents may need special considerations since they are difficult to mix and saturation solubility is reached later due to the slower diffusivity of molecules in these media [120]. When solubility and dissolution testing is applied in later phases to test product performance, stability, and formulation equivalencies or to establish BCS classification, clear specifications exist for both mixing and equipment. In this regulated environment, even a minor modification must be thoroughly evaluated during method development and validation before acceptance [71,99, 184–186].

16.5.2.5 Solid–Liquid Separation. Depending on the solubility and dissolution method used, solids need to be removed before a solute can be analyzed. This can be done by centrifugation or filtration. Centrifugation is a fast and easy method that is commonly used for solvents that are difficult to filter and reported results were comparable to those of filtration [158,187]; however, floating particles can cause problems [120,186]. In most situations, filtration is the method of choice. It is faster than centrifugation and filtration devices with largely different properties (filter material, surface area, pore size) and formats (single to 384 well) are commercially available for almost any application. Known problems with filtration are (i) compound losses by filter sorption of hydrophobic and poorly soluble compounds, (ii) incompatibility of some solvents with certain filter materials, and (iii) difficulties to filter highly viscous solvents. The latter two issues may be addressed by replacing filters by more resistant material [188] and by centrifugation at high g -forces to force the solvent through the filter [161]. Common approaches to address compound sorption to filters are prerinsing of filters with saturated compound solutions, discarding the

first fraction of filtrate, or using assay protocols that expose filters already during the incubation to saturated drug solutions such as the Whatman UniPrep[®] filter [156,189] or the SORESOS method [163]. Another approach might be the use of hydrophilic Polyvinylidene fluoride (PVDF) membranes for filtration, which showed the lowest sorption compared to other filters for the majority of compounds [120,156,190–193]; except for a recent study where hydrophilic polycarbonate filters were superior [182].

16.5.2.6 Solute and Solid Analysis. In a number of solubility and dissolution protocols, the compound in solution is directly measured by optical methods without removal of solids. In kinetic solubility studies (Section 16.5.3.1), increasing amounts of dissolved compound are added to the solute until precipitation occurs and the kinetic solubility is defined as the concentration preceding the point at which it occurs. The formation of precipitates is detected either indirectly by the increase in UV absorption or directly by a nephelometric turbidity detector [194,195]; in-depth discussions of the pros and cons of these techniques can be found elsewhere [153,196]. The solubility of ionizable compounds can also be directly measured by potentiometric methods, which detect a shift in pH values due to drug loss from solution by precipitation. Commercially available systems are the pSol Gemini [189,197] and the Cheqsol system [198]; their differences have been addressed briefly by Alsenz and Kansy [120]. In powder and intrinsic dissolution studies, the increase in drug in solution as a function of time may also be directly measured by *in situ* fiber optic dip-probe methods without removal of solids [199,200]. Miniaturized versions of these systems have recently been introduced and compared to USP methods [201–203]. Other less common systems for the detection of powder dissolution without prior separation use scattering of laser light from the particles in a liquid medium [204] and ultrasound [205].

In the majority of solubility and dissolution protocols, solutes are first separated from solids by filtration or centrifugation before analysis (Section 16.5.3.2). The compound in solution is then quantified by a UV plate reader [120,190,206], conventional high performance liquid chromatography (HPLC) analysis [120,207] or ultrafast HPLC systems [158,161,163]. In contrast to HPLC, the UV plate reader methods typically work only in the microgram to low milligram range, cannot differentiate between compound and degradation products, and may not work with solvents that have a high intrinsic background. Solubility in organic solvents may still be quantified by gravimetric analysis [188,208].

For the generation of high quality solubility and dissolution data, results have to be related to compound's solid state properties. Therefore, residual solids should always be analyzed for polymorphic changes with appropriate techniques such as X-ray powder diffraction (XRPD), Raman spectroscopy, infrared (IR) or terahertz spectroscopy. Some published protocols require a workup of samples before XRPD [209], others allow direct transmission XRPD analysis of residual solids on commercially available 96-well MultiScreen[®] solubility plates after filtration [163]. Direct measurements of polymorphic changes in slurry during or at the end of experiments is also feasible with Raman [163,188,210]. Optical microscopy with polarized light can be another option, however, it might be limited to the detection of drastic changes of solids such as amorphous–crystalline and crystalline–amorphous transformations or

significant changes in crystal shape and/or size [161,207]. A drying step may convert hydrates to the anhydrate.

16.5.3 Solubility Assays

The solubility assays applied in discovery and development combine the elements described in the previous section and the assays focus on the different key questions discussed in Section 16.5.2.1. Driving factors and considerations behind the development of specific assays are usually compound availability, throughput, costs, time, budget, available infrastructure, equipment, human resources, type of solubility addressed (kinetic vs. equilibrium), and quality of data. This results in largely different workflows and technologies used. Table 16.2 summarizes a number of them sorted by type of solubility addressed to better visualize common elements, differences, and trends among the various assays, the list being far from completeness.

16.5.3.1 Kinetic Solubility Protocols. Kinetic solubility assays are usually run in 96- to 384-well format and have medium to high throughput formats. The average test volume per assay is 0.1–0.3 mL and for a single data point, less than 1 mg of compound is required (in Table 16.2, mM values from publications were converted to mg/mL assuming an average compound MW of 500). Therefore, the solubility range addressed is ≤ 1 mg/mL and in most cases ≤ 0.3 mg/mL. The compound is added as solution in DMSO or in other organic solvents to the solvent of interest by robotic systems. After shaking for a few minutes to several hours at room temperature (RT), the compound in solution is quantified after filtration through 0.45- μ m filters by UV detection or indirectly by measuring precipitation with nephelometry. Precipitated solids and the final pH of solutions are not analyzed.

This setup of kinetic solubility assays is typical for discovery. It is adapted to other microtiter-plate- and DMSO-stock-solution-based automated screening protocols in this phase, and similar to other assays, the long-term stability of compounds in DMSO stock solutions can sometimes affect the outcome of studies [154,225]. Also, the organic solvent introduced into aqueous solutions in concentrations of 0.5–5% [120] can act as a cosolvent and enhance the solubility of some compounds [190,207,211,226]. Therefore, kinetic solubility is likely to overpredict thermodynamic solubility. Measured solubility values are expected to differ between different kinetic methods, since precipitation is a kinetic phenomenon that depends on a multitude of factors such as initial compound concentration in DMSO stock, time, temperature, mixing efficiency, and/or ability of compounds to stay in solution in supersaturated form. Nonetheless, kinetic solubility studies are suitable for the discovery stage for categorization or rank ordering of compounds, identification of solubility liabilities, comparison of hit-dose response values with apparent solubility values, guidance for chemists, and selection of development candidates [120].

The importance of equilibrium solubility values for decision making is increasingly recognized by discovery chemists. They realized that kinetic solubility neglects the solid state properties of a compound and that the promotion of drug candidates based on overestimated kinetic solubility values can have detrimental effects on any subsequent development plans and options [100]. Therefore, a number of protocols were established that tried to now address equilibrium solubility also without sacrificing the existing, compound-saving, rapid workflows established for kinetic solubility

TABLE 16.2 Summary of Representative Kinetic and Equilibrium Solubility Protocols

C, centrifugation; H, high; M, medium; Neph, nephelometry; U, unstirred; Cd, compound dependent; I, intrinsic; Ma, manual; Ro, robotic; UPLC, ultrahigh pressure liquid chromatography; E, equilibrium; K, kinetic; M, microscopy; SF, shake flask; US, ultrasound; EoE, end over end; L, low; MS, mass spectrometry; Sh, shaking; UV, ultraviolet; F, filtration; LC, liquid chromatography; N, no; St, stirring; Y, yes.

determination (Table 16.2, K/E). Two strategies are followed: one extends the equilibrium time of existing kinetic solubility protocols and the other uses solids generated from dried stock solutions.

The first approach increases the time between addition of the compound stock solution to the solvent and measurement of drug solubility from originally minutes to hours to a day or more. The extended incubation time favors precipitation of compounds from supersaturated solutions, conversion of solids to thermodynamically more stable forms (amorphous to crystalline, hydrates, etc.), and/or equilibration between solid and compound in solution. Incubation at 37°C is expected to speed up these processes further. Now, in a few cases, residual solid is also inspected for crystallinity, at least by optical microscopy [207]. Since equipment and protocols (except for time) remain basically unchanged, solubility ranges tested and uncertainties regarding cosolvent effects on drug solubility are similar to pure kinetic approaches. The latter is addressed by the second strategy. The compound is still distributed dissolved in organic solvent; however, the solvent is removed subsequently by evaporation. This allows adding higher amounts of compound per well, and hence larger solubility ranges can be addressed. It also eliminates the potential effect of organic solvent on drug solubility. The incubation time is extended as well to a day or more, stirring is preferred for mixing, and drug in solution is analyzed by HPLC or LC-MS after removal of solids by filtration or centrifugation. Similar to the first approach, initial solids or solids at the end of the experiment are not analyzed. Therefore, it cannot be guaranteed that the polymorph relevant for development has really been formed during the experiments or that equilibrium solubility has been achieved.

16.5.3.2 Equilibrium Solubility Protocols. Equilibrium solubility protocols usually start from powders that are well defined with respect to polymorphic forms and impurities. The assay formats vary from single vials to 96-well microtiter plates, and powders are usually distributed manually using balances (Table 16.2). Viable alternatives to this tedious and slow process can be volumetric devices [163] or distribution as suspension in nonsolvents [161]. The amount of compound added per data point is between 1 mg and about 20 mg and should exceed the expected solubility of the compound to guarantee the formation of a suspension at the end of the experiment. The volume of solvents in most protocols is below 1 mL, and solvents are added manually or, for the higher throughput formats, by robotic systems. Samples are then mixed by various procedures for one to seven days at RT or at 37°C, and the solute is analyzed after filtration by UV or HPLC. The target solubility range is between 1 and 300 mg/mL. In addition to these assays, a number of less common methods have been reported that use temperature ramps and DSC, thermogravimetry, or turbidimetric methods to address some more specific questions regarding compound solubility or dissolution (for references, see Table 16.2).

The presumably most famous method to determine drug solubility is shake flask that is often regarded as the “gold standard” for determining equilibrium solubility. However, the experimental details of the method have never been exactly defined, and hence very different protocols exist (Table 16.2). Shake flask methods can thus differ tremendously in almost all experimental parameters, and even extremely important ones such as examination of final pH of the solution and of residual solid are not always considered. Consequently, measured solubility values should not be taken as absolute. Frequently, values cannot be linked to solid state properties or pH, and

comparisons across different data set generated by the so-called “shake flask” methods may be problematic and error prone. Often, equilibrium solubility may also be affected by a variety of sometimes, unobvious factors [120]. Examples are the water content in oils, which decreases the solubility of steroids [227] or the overestimation of free drug concentration in filtrates due to nanoparticles or amorphous compound droplets passing filters. Moreover, some drugs form aggregates [228,229], nanofibers [230], or complexes with solvent constituents [231], and therefore, the real amount of free drug available, for example for absorption, will be much lower than expected. A number of partially and fully automated systems designed to measure equilibrium solubility are already commercially available [120]. Ideally, equilibrium solubility studies are performed with the most desirable physical form for development, which means with the most stable, crystalline polymorph with the highest possible purity. In most setups, equilibrium studies are used to confirm previous kinetic solubility results, to rule out potential artifacts, and to generate quality solubility data for formulation development, analytical development, and cleaning validation.

16.5.3.3 Intrinsic Solubility Protocols. The intrinsic solubility, S_0 , is the solubility of the uncharged species of a molecule. For neutral molecules, it is identical at all pH values; for ionizable compounds, it can be measured by potentiometric approaches (Table 16.2). In potentiometric titration, known volumes of strong acid or base are added to a vigorously stirred solution of test compound and the pH is recorded. Solubility is determined by the pH shift due to drug precipitation during the titration. The method is limited to ionizable compounds and does not take the solid state properties of precipitates into account. Potentiometric methods for the determination of solubility were first introduced by Avdeef [232], and an automated system, pSol, is commercially available [189,233]. The method is relatively slow but allows the generation of a pH/solubility profile with a single titration in about 8–24 h. A second method, termed *chasing equilibrium solubility* (CheqSol) was introduced by Stuart *et al.* [198] and is also commercially available [234,235]. This method enables concentrations of compounds to be established during the time course of precipitation and dissolution events. It allows determination of equilibrium, kinetic, and intrinsic solubilities within 20–80 min and has also been used for the investigation of supersaturation phenomena and for BCS classification of drugs [234,236] (Section 16.6.5).

16.5.4 Dissolution Measurement

Dissolution testing is an important tool in the development of drug characterization, BCS classification, identification of appropriate oral dosage forms, and BE testing. In contrast, dissolution testing in drug discovery is rare. A reason could be that standard solubility/permeability-type BCS representations do not readily show the importance of dissolution for the rate and extent of oral absorption, in particular for LS drugs, and hence it is neglected. However, this may result in wrong absorption predictions [e.g., MAD calculation (Section 16.3)] if calculations are solely based on equilibrium solubility and permeability. For example, a rapidly dissolving LS/HP compound (BCS class 2) with lower equilibrium solubility can exhibit a higher fraction absorbed than a slowly dissolving compound with higher equilibrium solubility (Section 16.4.1).

Shortage of candidate material can be another reason why dissolution is not tested in discovery. Traditional powder dissolution (Fig. 16.7a) and intrinsic dissolution testing (Fig. 16.7b) requires hundreds of milligrams of highly pure compound for single

Parameter		Affected by (examples)
m	amount of drug dissolved	
t	Time	
D	Diffusion coefficient	MW, complexation, soluble aggregates, temperature, viscosity
S	Effective surface area exposed to medium	Particle size and shape, particle agglomeration
h	Apparent stagnant diffusion layer thickness	Stirring rate, viscosity, particle size
h'	Effective stagnant diffusion layer thickness	'Reactive' media (e.g. ionization, complexation, buffering capacity)
$C_B [\text{Comp}]$	Concentration of 'complexed' drug in the bulk solution	
C_s	Saturation solubility at the surface of the solid	Salt form, crystal form, pH, pKa, 'reactive' media
$C_B(t)$	Concentration of drug in the bulk solution at time t	Sink conditions, volume of dissolution medium

Figure 16.7 Schematic presentation of (a) powder dissolution, (b) disc intrinsic dissolution, and (c) diffusion-controlled dissolution model according to the Nernst–Brunner equation. The table summarizes parameters that influence the amount of drug dissolved and gives examples for factors that affect them (Section 16.5.4).

measurements, which would then not be available for other, potentially more important experiments in this phase. Moreover, assays require large volumes (50–900 mL) of sometimes expensive biorelevant media, and assays are low throughput. Trials to reduce the volume and/or increase the throughput of dissolution assays are generally regarded with skepticism about the scalability of dissolution methods since dissolution measurement is affected by a large number of parameters (Fig. 16.7c) [201,237]. The most important ones can be derived from Equations 21.9, 21.21, and 16.25 and are briefly addressed subsequently.

The driving force for dissolution is the concentration gradient between the drug dissolved at the drug surface (C_s) and its concentration in the bulk at time ($C_B(t)$) (Fig. 16.7c). According to the equation (based on Eq. 16.9) in Fig. 16.7, the dissolution rate is highest when $C_B(t) \ll C_s$, which means under sink conditions where all dissolving compound is rapidly diffusing away from the surface of the solid drug. Such sink conditions are assumed when C_B is $<10\%$ C_s and are achieved in the USP methods by using large volumes of dissolution medium. However, for formulation

testing, large volumes may not always be favorable. Gu *et al.* [238] demonstrated that smaller, physiologically more relevant dissolution volumes predicted the BA of a salt of a weak base much better than the 1L standard approach, which masked the effect of formulation excipients on drug dissolution.

Most dissolution processes are diffusion controlled, and hence, agitation strength affects dissolution rate. Strong agitation reduces h , which is inversely proportional to the dissolution rate (Eq. 16.9). In particular, LS drugs may rapidly get close to their equilibrium solubility at the boundary layer and dissolution will be stopped or delayed without agitation [145,239]. The thickness of the boundary layer depends on the particle size. The smaller the particles are, the less affected the dissolution rate is by agitation, since the boundary layer thickness decreases and surface specific dissolution rates increase [130,131,143]. Thus, agitation intensities do not seem to affect dissolution rates of particles $<5\text{ }\mu\text{m}$ [131].

Dissolution is strongly affected by the composition of the dissolution medium. Ionic composition, pH, buffer capacity, and added excipients can influence the solubility and dissolution of a drug, and hence for the development of appropriate dissolution media, many factors have to be considered. In water, dissolving free acids lower and dissolving free bases raise the pH at the surface of the particle compared to the bulk solution and thus decreases their solubility C_S at the surface. According to Eq. 16.9, the drug then diffuses through the liquid UWL with the thickness h until $C_B(t)$ reaches C_S at $T = \infty$ (Fig. 16.7c). If a buffering species is added that shifts the pH to higher (for acids) or lower (for bases) values, it is expected that (i) the acid–base interaction at the interface will reduce the thickness of the UWL (h'), (ii) the larger difference between surface pH and pH in the bulk will act as a better sink, and (iii) C_S at the surface may increase. Together, these processes all favor a faster dissolution in the presence of buffers. Furthermore, the dissolution velocity often increases with buffer concentration [169,201] and the selected buffering species, for example, phosphate versus bicarbonate, can have a profound impact on dissolution rate and saturation solubility [240,241]. Neutral compounds are not affected by pH or buffering species. However, the dissolution rate of both neutral and charged drug species can be greatly modified by a number of excipients in dissolution media. Excipients are often added (i) to increase the solubility of less soluble drugs to measurable levels, (ii) to guarantee complete dissolution of poorly soluble drugs, (iii) to simulate *in vivo* conditions, (iv) to improve wetting of particles, (v) to deaggregate particles, and/or (vi) to provide sink conditions without increasing the aqueous sink volume. Water–cosolvent mixtures is one approach that can improve both drug solubility and dissolution [242]; however, dissolution testing of drug products may need special considerations [243,244]. Another common approach is to enhance solubility by adding micelle-forming surfactants. Micelles also “react” with free compound and thus reduce h' . They exert their effect on both ionized and unionized molecules, and the total solubility C_S is the sum of free solute form(s) and micelle-solubilized form(s). Compared to the often high enhancement in solubility, the increase in dissolution rate is usually much lower. The reason is that solutes in micelles diffuse slower than single molecules because of the much larger diameter of the micelles, hence micelles have a lower apparent diffusion coefficient. For example, the solubility of griseofulvin in 60 mM sodium dodecyl sulfate (SDS) increased ~ 107 -fold, whereas its dissolution rate rose only ~ 30 -fold. Also, the diffusivity of micelles dropped about 10-fold compared to that of free griseofulvin ($11 \times 10^{-6}\text{ cm}^2/\text{s}$) [245]. Similar examples have been reported for Danazol [246],

fenofibrate [247], and ketoprofen [248], the latter showing an even 30-fold decrease in diffusivity. Other reported factors affecting dissolution rate in the presence of SDS are changes in apparent pK_a value of ionizable compounds with increasing concentrations [249,250] and repulsive forces between charged micelles, which reduced micelle diffusivity and may need pH and ionic strength control [246,248]. To generate sink conditions, surfactants may be replaced by CD in dissolution media if the drugs form complexes with them [251]. As a result, solubility and dissolution rate increase [252] and diffusivity of complexes decreases; however, diffusivity velocity decreased only by a factor of two since complexes are smaller than micelles [253]. Combinations of surfactants and CD may result in more complex situations. Some surfactants compete with drugs for binding to CD [254,255], and this affects both the solubilization capacity of the medium [252] and the diffusivity of the various molecular species, the overall effect depending on the drug/cyclodextrin/surfactant ratio [256–258]. If viscosity enhancing agents are added, the diffusion layer thickness of particles is expected to increase and the diffusion coefficient to decrease. Dissolution of small particles seems to be less affected by viscosity enhancing agents than larger particles.

The surface area available for dissolution is another important factor in powder and solid dosage form dissolution studies. Particle size reduction is expected to increase surface area available for dissolution and particle aggregation to decrease it. Experimentally, particles with a size of $1.5\text{ }\mu\text{m}$ showed indeed a much faster dissolution than $12\text{-}\mu\text{m}$ particles [173], and agglomerates of furosemide [259] or oxazepam [260] exhibited decreased dissolution rates. *In vivo*, particle size reduction of felodipine (solubility in saline: 0.077 mg/mL) from $125\text{ }\mu\text{m}$ to $8\text{ }\mu\text{m}$ resulted in a 14-fold increase in AUC in dog [261].

In vitro dissolution results may be used as a surrogate to predict the *in vivo* performance of drugs and formulations, particularly of BCS class 2 and 4 compounds. In the GIT, bile salts and lecithin act as physiological surfactants that improve wetting and solubility of lipophilic compounds. Media designed to simulate this *in vivo* situation have been introduced to establish IVIV correlations [166], and efforts to further improve them are ongoing [262,263]. Compared to many surfactants with micelle aggregation numbers >60 [245], bile salt structures give values <10 [246], hence bile salts are expected to solubilize less compound. Lecithin added to bile salts (mixed micelles) leads to an improvement of the solubility and of the dissolution rate of some LS drugs [264]. However, the effective diffusivity of mixed micelles is approx 100-fold lower than in comparable taurocholate solutions since lecithin also increases the micellar diameter [264], the increase depending on the dilution [131]. Furthermore, the buffer capacity of previously used FaSSIF and FeSSIF media [166,168] were too high compared to values measured in human aspirates [265], hence self-buffering effects may have been underestimated with these media (Section 16.5.1.3). Recently, this was corrected by the introducing new media with lower buffer capacity [169].

Other applications for dissolution testing are the screening and characterization of salts [266], cocrystals [267,268], and polymorphic forms [269,270] for appropriate form selection for development. As described in Section 16.5.2.6, their solid state properties need to be carefully monitored at the end of the dissolution study since they may rapidly dissolve, form supersaturated solutions, and then precipitate as crystalline or amorphous material. Dissolution studies with cocrystals have recently been reviewed by Schultheiss and Newman [128]. Hydrate formation also needs to be carefully investigated since it can reduce drug dissolution rate [271] and solubility [138] and can affect

the outcome of *in vivo* oral absorption studies [270,272]; however, reduced solubility does not always correlate with reduced dissolution rates [138].

Another application of dissolution testing is the screening for excipients (polymers, surfactants, etc.). These studies are useful to identify formulations with enhanced dissolution rates, crystallization/precipitation inhibitors, or stabilizers, for example, for suspension formulations. In most of these studies, the effect of excipients on drug dissolution is tested after physical mixing [273], after cogrinding [274], or after preparation of solid dispersions or solid solutions by spray drying [275] or hot melt extrusion [273,276]. More recently, excipients have also been added directly to dissolution media or tested in slurry experiments [272,277,278]. Changes in solid form such as hydrate formation are either analyzed *in situ* [279–281] or at the end of the experiment [272].

Dissolution testing has become an important tool in development for testing of drug powders and dosage forms and is an official test used by pharmacopoeias [172,176]. Most of the testing is performed in quality control to confirm or test product consistency. In research and development, the focus is more on the prediction of the *in vivo* behavior of a drug or a drug product and on the identification of appropriate formulations. Therefore, a number of different testing protocols and apparatus have been designed to address the two types of dissolution methods, powder dissolution, and intrinsic dissolution. Some representative protocols are summarized in the following two sections and in Table 16.3.

16.5.4.1 Powder Dissolution. The dissolution tests listed in the USP are designed for oral solid dosage forms, and currently, there is no official powder dissolution test [176]. However, the general principles of these tests should also be applicable to powders, hence compendial apparatus are commonly used for powder testing. The most frequently used USP apparatus are shown in Fig. 16.8 including a short summary of their specifications and applications (see also www.sotax.com, www.erweka.com, www.varianinc.com, <http://www.distekinc.com>). A number of studies have addressed and compared their use and value for specific applications [176,237,282,290,291]. Details of the common elements of dissolution assays have been discussed before (Section 16.5.2).

Table 16.3 lists a number of representative protocols used for powder dissolution testing, the table being roughly sorted by volume of dissolution medium used per assay. The operational volumes of the rotating basket (USP 1 apparatus) and of the rotating paddle (USP 2 apparatus) are in the range of 500–900 mL (Fig. 16.8). Powder and medium are distributed manually, and throughput is usually low; however, fully automated systems with 10–15 dissolution test vessels are now commercially available [292,293] (see also www.sotax.com, www.erweka.com). Systems with scaled-down baskets and vessels are also available [237,294]; however, their use may be limited to LS compounds and low dose solid dosage forms in terms of maintaining sufficient sink conditions. The USP 3 (BioDis) (www.varianinc.com) and USP 4 (flow-through cell) can be used for dissolution testing in only one medium or in several media to imitate passage through the GIT (Fig. 16.8). The BioDis system uses cylinders sealed with membrane filters to retain powders or disintegrating particles inside the vessels when they move from one medium to another. The medium volume is in the range of 50–200 mL [286]. In the open loop flow-through cell, one medium is pumped through the dissolution cell and, if needed, is simply replaced by another. In closed

TABLE 16.3 Summary of Representative Powder and Intrinsic Dissolution Protocols

Name	Type	Format	Throughput	Volume (mL)	Compound/ Point	Compound Distribution	Evaporation	Solvent Distribution	Mixing	Incubation Time (h)/ Temperature (°C)	Solid/ Liquid Separation	Solid Characterized	Liquid Analysis	pH	Ref.
USP 1	PD	1	L	900	Cd	Powder	—	Ma	St	-/37	F	N	UV	N	282,283
	PD	1	L	900	Cd	Powder	—	Ma	St	—	N	N	UV turbidity	N	284

loop systems, the medium is continuously pumped through the cell and volumes can be as low as 15 mL [237,295,296].

Compound consumption in USP apparatus depends on the expected saturation solubility and is typically in the range of 100–500 mg per dissolution experiment. For most discovery setups, this is far too high and several small-scale dissolution systems have been established for screening. The focus of these studies is formulation and excipient screening; these studies are performed at RT, whereas compendial tests are run at 37°C. Protocols are adapted to the needs of discovery and early development, and compounds and excipients are distributed in organic solvents, which are subsequently removed by evaporation [159,165]. These protocols neglect the solid state properties of the drug after evaporation; however, they may be useful for identifying formulations that dissolve more rapidly or form supersaturated solutions and improve oral BA [160] (Sections 16.6.3 and 16.6.5). These applications may also be addressed by the high throughput microarrayed compound screening system (μ ARCS) [287]. About 40 nL of a 5 mM solution of compound in DMSO is spotted onto polystyrene sheets and dried. An agarose gel is placed on top of it, and the time-dependent diffusion of compound into the gel is monitored in excised gel pieces by LC-MS.

16.5.4.2 Intrinsic Dissolution. The measurement of intrinsic dissolution rate (IDR) is useful for the characterization of pure drugs, for mechanistic studies, and for comparing different drugs or solid forms of a drug. For these studies, compressed disks of drugs with a known diameter are produced using a punch and die, and then, a defined single surface area of the disk, typically 0.5 cm², is exposed to the medium. During the experiment, the surface area is taken as constant, and if all other conditions (volume,

temperature, agitation, pH, etc.) are also fixed, the IDR can be directly calculated from the amount of drug released per unit surface area and time (Eq. 16.9). Such comparisons are difficult to perform in powder dissolution studies since the initial particle size and particle size distribution are often not known and the surface area exposed to the medium constantly changes throughout the experiment (Section 16.5.1.3).

IDR is traditionally determined using the rotating disk system (USP Wood apparatus). It is similar to the USP 2 apparatus shown in Fig. 16.8, however, the paddle is replaced by a rotating holder carrying the die with the compressed drug disk (Fig. 16.7b). The die is inserted into the dissolution medium at a defined distance from the bottom and rotated at constant speed at 37°C [151]. However, in a modified system, the stationary disk system, the design of the USP 2 apparatus is kept, the die is placed at the bottom of the vessel, and the dissolution medium is moved over the disk by the paddle [185]. The volumes used are between 200 mL and 900 mL, and about 200–500 mg of drug is required per disk.

An alternative to USP 2-apparatus-based systems is the modified channel flow-through system. Between 150 mg and 200 mg of a drug is compressed with a single punch tableting machine, mounted into a tablet holder, and then placed into the center of a cell with an inlet and an outlet for the medium [282]. In dissolution studies, the medium is pumped through the cell with flow rates between 1.7 mL/min and 20 mL/min, and the dissolved compound is detected using a UV–VIS spectrophotometer. In a modified system, the cell is equipped with a quartz sight window to allow *in situ* Raman measurements for the direct identification of solid phase changes [280]. Another system combines a flow-through cell system with a rotating disk [288]. It requires only 5 mg of drug to make a compressed disk in a hole in a magnetic bar. The bar is inserted into a 0.3-mL chamber of a flow-through cell and rotates during the dissolution experiment.

Recently, Berger and colleagues [203] introduced a new, miniaturized rotating disk IDR measurement system that has gained considerable interest. It uses a Mini-IDR™ compression system (Heath Scientific, UK) to make a disk with a surface area of 0.07 cm² from about 5 mg of drug powder in a die [201]. The die is inserted into a Teflon carrier with an embedded stir bar and placed into a vial with 10–15 mL of medium. The carrier is rotated during the dissolution experiment, and the drug released is determined in a μ DISS ProfilerPLUS™ instrument (pION) using a fiber optic dip probe. Experiments are performed at 37°C in up to eight parallel channels. The data from the new miniaturized IDR instrument showed excellent correlation to literature values from traditional IDR measurements and suggests that IDR measurements can be scaled down to the needs of drug discovery without sacrificing data quality [201]. For LS compounds (IDR <0.1 mg/min/cm²), compound consumption may even be reduced further to 0.06 mg per experiment, since IDR may be calculated from powder dissolution experiments without prior knowledge of particle size and shape [202].

The miniaturized intrinsic dissolution screening system (MINDISS) also consumes only 2–5 mg of compound per disk [289]. Disks with a surface area of 0.031 cm² are made in custom-made holders and inserted into 0.25 mL of dissolution medium in 96-well microtiter plates. Similar to Caco-2 transport experiments, holders are transferred into new wells with fresh medium after a predetermined time to achieve sink conditions or disks are transferred to another medium to simulate GI passage. Samples are filtered, and the dissolved compound is finally quantified by ultrahigh pressure liquid chromatography (UPLC).

All miniaturized IDR protocols have the option of obtaining XRPD or Raman data on the initial disk and the remaining disk to identify solid-form modifications during dissolution studies. Although this is not routinely done, the correlations obtained between traditional rotating disk methods and the new compound-saving, miniaturized IDR methods are already excellent [201,288]. Therefore, dissolution as a rate-limiting step in oral absorption can and should now be addressed earlier and become an integral part of late discovery/early development selection strategies. Even if compounds do not yet have the required final purity, small-scale dissolution testing offers the opportunity to screen, compare, and select polymorphs, salts, and cocrystals for development much earlier and thus hopefully reduce later-stage issues due to inappropriate solid state properties.

16.6 IMPACT OF SOLUBILITY AND DISSOLUTION ON FORMULATION STRATEGY

16.6.1 General Considerations for Formulation Strategy

In principle, the very general equation (Eq. 16.4) [or the easier-to-approach MAD equation (Eq. 16.5)] and the Nernst–Brunner equation (Eq. 16.9) already describe all options formulators have to influence drug absorption. In theory, each and any of these parameters can be modified by formulation, although not to the same extent. Realistically, C_S and the dissolution rate are the two factors where formulators can do most to improve absorption since drug solubility can vary over six orders of magnitude ($\sim 0.1 \mu\text{g/mL}$ – 100 mg/mL) [43] and dissolution rate up to 400-fold, for example, in response to pH [151]. In contrast, permeability varies only about 50-fold (hum k_a ranges from 0.001 – 0.05 min^{-1}) [43] and physiology-related parameters (transit time, surface area exposed to drug, water volume, etc.) can, if at all, be influenced only within very small limits. Therefore, at least the solubility, dissolution, and permeability characteristics of a drug have to be known before one can decide on which drug delivery technology to use in which development phase for the delivery of a defined target dose to a specific species.

LP is still an unmet challenge and difficult to address by formulation approaches. Depending on the underlying reasons for poor membrane permeability, formulation may or may not increase the absorption of BCS class 3 and 4 compounds (Section 16.4.1). If low lipophilicity comprises absorption, transient opening of the tight junctions with excipients may improve absorption of polar compounds [84]. If efflux mechanisms and/or metabolism limit absorption, excipients inhibiting them may be used in formulations to enhance the extent of absorption [297] (Section 16.8). In both cases, the drug and excipient must be delivered to the site of absorption simultaneously and potential toxic effects related to the excipients have to be evaluated carefully. As an alternative, the solubility of drug in solution can be increased as discussed later (Section 16.8). This will increase the extent of absorption per se (Eq. 16.4) and above a certain level, saturate efflux mechanisms and/or metabolism, which will further improve absorption.

For the majority of compounds at present, solubility and/or dissolution are the limiting factors. In recent years, the percentage of LS lead compounds has significantly increased, and in many development pipelines, 60–70% of the new NCEs now fall into BCS class 2 (Section 16.4.3) [97]. Therefore, comprehensive assessment of solubility

and dissolution is essential. It serves as guidance for the formulation scientist and sets the stage for formulation development. Fortunately, solubility and dissolution liabilities can be addressed by a large variety of formulation approaches as is discussed below.

16.6.2 Decision Trees for Formulation Development

A considerable number of very different decision trees and flow charts have been published for formulation selection, the schemes considering largely different criteria for decision making. Some schemes cover only specific development phases [298–303], others focus more on when to apply standard, intermediate, or enabling technologies for drug delivery [298,304] or when to use specific technologies such as nanosuspensions [302,305], lipid formulations [306,307], or absorption-window-specific technologies [308]. Special formulation decision trees also exist for acute PK/PD studies and for long-term studies [298,299,309], and particularly, excipient effects on PK/PD studies [310] and the potential toxicity of some excipients in chronic studies need thorough considerations [299,311]. Depending on the route of administration, for example, intravenous versus oral [301,302,304,312,313], and the species, for example, human versus animal [96,304], decision trees may also differ. Decision trees purely built on physicochemical properties such as log D, solubility, IDR, solid state properties, or MP are rare [312]. More recently, the BCS classification scheme has been used for the selection and design of formulations [96,97]. The BCS (Section 16.4.1) combines dose with solubility, permeability, and dissolution and the derived parameters D_o , D_n , and A_n (Section 16.3) may be used as more easily accessible decision criteria for building up simplified decision trees [314,315].

The general issue with decision trees is that it tightly couples knowledge and the use of knowledge in individual decision paths, and hence all possible decision paths and criteria have to be present in the tree. If information is missing, decisions can not be made; examples are the missing criteria for high and low MP, log P, and dose in the nanosuspension scheme from Rabinow (Fig. 16.1 in Ref. 305) and the decision tree from Gardner *et al.* (Fig. 16.5 in Ref. 316), which cannot be followed if a compound does not crystallize. Moreover, many decision trees may require techniques or measured physicochemical properties that are not available everywhere or consume too much compound to be practicable. Therefore, the subsequent formulation section does not show yet another decision tree (that might not be applicable to the readers situation) but provides some basic insight and guidance to the reader on the rational behind *oral* formulation development to foster the setup of individual formulation strategies. Parameters that can be modulated by formulation are addressed, potential formulation techniques are presented, and the pros and cons of these techniques are discussed. Strategies to overcome permeability-limited absorption are not discussed as mentioned before (Section 16.6.1).

For scientists outside formulation departments, formulation development is often confusing. Formulation scientists have a multitude of options to combine formulation principles, technologies, and excipients to address specific delivery issue, and often, they forget to communicate the rational behind a formulation. In principle, the strategy in formulation development is very simple and consists of the following steps:

1. collect or measure the most important physicochemical properties of a drug
2. identify the rate-limiting steps in absorption (Section 16.3)

3. react accordingly by building up a formulation strategy that is adapted to the development phase, therapeutic area, target dose, species, and available formulation technologies and resources, and, not to forget,
4. keep an eye on potential excipient toxicity, on the overall formulation strategy for entry into human, and on potential backup formulation strategies.

Therefore, a rational, fact-based formulation development starts with the collection of a number of key parameters that need to be known from the very beginning, for example MW, log P, polar surface area (PSA), pK_a , solid state properties, solubility, IDR, chemical stability, and permeability. Also important are the details behind reported values; for example, the formulator should know which type of solubility (kinetic/equilibrium, final pH, amorphous/crystalline starting material, changes in solid state properties, etc.) or permeability (PAMPA, cell based, at which pH, etc.) was actually measured or how the compound behaved macro-/microscopically in the respective assays (floating, aggregation, oiling-out, initial complete dissolution then precipitation, etc.). In some cases, this may already give a clue on potential formulation strategies and technologies and avoid misinterpretations. The challenge for formulators is then to translate this information into appropriate formulations. For compounds with HP, formulation can modulate oral delivery at the levels of dissolution, solubility, and precipitation as shown in Fig. 16.9. The discussion of formulation principles will basically follow the idea of “spring” and “parachute” recently reviewed by Brouwers *et al.* [134]. In Section 16.6.3, solid formulations with increasing energy of the solid are presented, which address enhancement of dissolution rate and/or increase of apparent solubility of drugs. In Section 16.6.4, solution formulations increasing a drugs’ kinetic solubility are presented, and in Section 16.6.5, the principles of precipitation inhibition are discussed.

16.6.3 Formulation Strategies Improving Drug Dissolution and/or Apparent Solubility

Drug in solid dosage forms or in suspensions needs to dissolve first before it can be absorbed from the GIT. For rapidly dissolving compounds, the saturation concentration C_S in the GIT is reached almost instantaneously and the rate of absorption is then maximal (Eq. 16.4) (Figs. 16.1 and 16.9⓪). For HP compounds ($A_n > 1$) with $D_o \leq 1$ (BCS class 1) (Sections 16.3 and 16.4.1), the total dose will dissolve and will be absorbed within the absorption window ($D_n > 1$), whereas for compounds with $D_o > 1$ (BCS class 2), only a fraction of the dose will be absorbed (solubility-limited absorption). If dissolution is slow, $D_n < 1$, the compound will be absorbed faster than it dissolves, hence C_S will not be achieved and the extent of absorption will be lower (dissolution-limited absorption) (Figs. 16.2 and 16.9). In these cases, several formulation strategies can be applied to speed up drug dissolution rate (to push 2 to 1 in Fig. 16.9).

16.6.3.1 Modification of Surface Area. The first dissolution-enhancing approach is to optimize the exposure of available surface area of particles to the solvent. In suspensions, hydrophobic particles often agglomerate to reduce their surface energy, which will decrease the dissolution rate according to the Nernst and Brunner equation (Eq. 16.9) and introduce kinetic hindrance to the diffusion process. Agglomeration

Figure 16.9 Drug concentration–time profiles for different formulation approaches. The schematic representation shows formulations maximizing drug dissolution rate (Section 16.6.3) and illustrates the “spring/parachute” approach for solubilizing formulations (Section 16.6.4) and for formulation inhibiting drug precipitation (Section 16.6.5).

can be inhibited by adding steric polymeric stabilizers such as polyvinyl pyrrolidones, pluronics, and cellulose derivatives or surfactants such as polysorbate 80, lecithins, cholic acid derivatives, or sodium lauryl sulfate to the suspension vehicle. A more in-depth description of the underlying mechanisms can be found in Refs. 305,317. In practice, on a small scale, homogenous suspensions may be obtained by intense stirring, which will support deagglomeration due to the shear forces. However, air incorporation should be avoided since air may form a cushion around hydrophobic particles and separate them from the solvent. For larger scale deagglomeration, short cycles in a Dyno® Mill or a Dispermat® may be used.

Particle size reduction is another method to improve the dissolution behavior of drugs (Section 16.5.1.3) (shift 2 to 1 in Fig. 16.9). With decreasing particle size, the surface area increases for a given mass, the diffusion layer thickness decreases, and thus the dissolution rate increases (Section 16.5.1.3). In addition, smaller particles are energetically unfavorable because of the higher interfacial energy and are subject to preferential dissolution. In some cases, their apparent solubility can be above C_S , leading to precipitation and growth at the surface of larger particles (i.e., Ostwald ripening) since bigger particles inversely have a lower dissolution rate and saturation solubility. The speed of the growth of large crystals at the expense of small ones due to Ostwald ripening decreases with decreasing saturation solubility of the drug, and Ostwald ripening may be circumvented by preparing suspensions with largely narrow particle size distribution. For spherical particles, the reduction in size is proportional to the increase in surface area, that is, a 10-fold decrease in size results in a 10-fold increase in specific surface area [177] and hence an only 10-fold increase in dissolution

rate may be achieved. Size reduction to the submicron range has found considerable interest for drugs that are difficult to formulate by other methods, and in particular, high dose, LS drugs with a high MP and a high lipophilicity profit from particle size reduction [305]. Such drugs, formulated as nanosuspensions, showed significantly increased oral absorption, for example, danazol [318], naproxen [319], and aprepitant [320]. However, a greatly improved dissolution rate *in vitro* does not always translate into higher absorption *in vivo* since other factors such as fasted and fed state or physicochemical properties of drug also seem to play a significant role [321]. Mucoadhesion, which may increase GI transit time, is discussed as another mechanism to explain the enhanced oral BA of nanosuspensions [305]. Compared to microsuspensions, nanosuspensions have several advantages: they often show (i) a higher BA, (ii) a less variable and less food-dependent exposures [319], (iii) a faster onset of action, and (iv) a more linear increase in exposure with dose and they can also be used for intravenous and subcutaneous drug administration with PK, often equivalent to that of a solution formulation [302]. Nanosuspensions, can be prepared at high weight-to-volume loading, for example, for toxicity studies, and since no cosolvents and only small amounts of excipients are required, the toxicity of vehicles is usually much lower than with other formulation approaches. However, because of the high surface energy, nanosuspensions are more prone to agglomeration, and thus, stabilization is very important to retain the large surface area. Miniaturized screening systems for their preparation and characterization and for the identification of surface-stabilizing excipients have been reported recently [322,323]. Standard techniques for producing micro-/nanosuspensions are media milling and high pressure homogenization, and both top-down (breaking down of bulk material) and bottom-up (building up from solution) technologies are applied. Extensive reviews discussing their advantages and disadvantages, the use of stabilizers, and the characterization of nanosuspensions are available in this area [319,324,325]. Small-scale systems for the preparation of 2–5 mL volumes of micro-/nanosuspensions for early phases PK/PD studies exist, for example the Mixer Mill from Retsch (www.Retsch.com) and the NanoMill® from Elan (www.elandrugtechnologies.com). The mechanical impact generated during milling in top-down approaches may cause chemical degradation and/or physical conversion of drugs. In particular, the latter is often ignored in early phases. Formation of new polymorphic forms, hydrates, or amorphous material with different dissolution behavior and apparent solubility during milling can have a huge impact on drug exposure and on the outcome of PK/PD studies. Nanosuspensions are also an option in clinical trials to improve exposure and to reduce food effects and variability.

16.6.3.2 High Energy Solids. Another option to improve drug dissolution is the use of higher energy (metastable) solid forms, which affects both the dissolution rate and the apparent solubility of drugs (Fig. 16.9, shift 2 to 1 and 2 to 3). In particular, amorphous forms have a higher energy state than the most stable crystalline form and, thus, their solubility and dissolution rate are higher [135]. However, if the apparent solubility exceeds the C_s of the most stable polymorph and supersaturated concentrations are formed, crystallization of amorphous material may occur. Crystallization at the surface is faster than in the bulk, and even a thin layer at the surface may already significantly slow down dissolution [281]. Thus the conversion rate of the metastable amorphous to the stable crystalline form has to be slower than the dissolution rate of the drug to take advantage of the amorphous form. Amorphous formulations without

stabilization are challenging with regard to reproducibility, since crystallization may occur at any time during manufacturing, storage, or *in vivo* absorption because of many factors such as agitation type and speed, medium composition, temperature, or surfaces properties. Also, amorphous forms often tend to adsorb moisture, which may lower its glass-transition temperature and facilitate recrystallization. Amorphous solids are often generated unintentionally in discovery chemistry programs, and exposures achieved with these materials are difficult to reproduce at a later time, even with the same batch. The manufacturing of pure amorphous material without stabilization in this phase is not common and not desirable; however, partially or completely amorphous solids may be generated during formulation preparation, for example, by the energy entry during wet milling. Therefore, monitoring of amorphous–crystalline transformations in suspensions, at least by polarization microscopy, should be performed to allow informed decisions, particularly if PK and PD results of amorphous and crystalline compounds are compared and used for candidate ranking. The gain in solubility using higher energy crystalline forms is usually less than with amorphous material and is typically in the range of <2 [126]. If they are used as starting materials, solid transformations are more difficult to follow and will require Raman or XRPD analysis. Nonetheless, this additional characterization can help (i) to identify polymorphism and hydrate formation issues early on, (ii) to improve the quality of data, and (iii) to better differentiate observed *in vivo* variability in exposure related to solid state changes in formulation from other factors [138,270,280].

16.6.3.3 Multicomponent Drug Solids. The dissolution rate of drugs may also be modulated by combining them with partner molecules, that is, by preparing salts, cocrystals, hydrates, cyclodextrin complexes, and solid dispersions/solutions. These approaches alter the chemical and physical solid state properties of drugs and are designed to increase their dissolution rate and, more than the previously discussed concepts, their apparent solubility (Fig. 16.9, ③).

16.6.3.3.1 Salts. Salt formation is limited to ionizable drugs, and salt selection largely depends on pK_a values. The selection of the “best” salt for development is not trivial, and for a discussion of criteria, the reader is referred to the book by Stahl [326]. For acidic drugs, sodium and potassium salts are often first considered; for basic drugs, the hydrochloride salts are the most common ones. As a rule of thumb, the pK_a difference between an acid and a base should be three or more to form stable salts. The solubility of a salt in aqueous medium is higher than that of a nonionized species, and when salts dissolve, they act as their own buffer and change the microenvironmental pH and solubility in the diffusion layer. Drug solubility is then governed by the solubility in the diffusion layer. Depending on the pH of the GI fluid, a drug may precipitate as nonionized fine amorphous or crystalline particles when it diffuses out of the diffusion layer. In many cases, this precipitate consists of prewetted fine particles with a very large surface area, which can rapidly redissolve when additional fluid becomes available. Therefore, a salt may achieve a higher exposure than the native drug [327]. In contrast, when the intrinsic solubility of a drug is very low, its unionized form may precipitate very close to the dissolving surface and coat the surface. This may prevent further dissolution of the salt or deaggregation of particles of a solid dosage form and hence result in lower exposure as shown for example, for sodium warfarin [328]. The formulation of a salt is often challenging since, in particular, in

suspension formulations for small animal species, salt may rapidly convert to the free form if inappropriate vehicles were selected.

16.6.3.3.2 Cocrystals. Pharmaceutical cocrystals are composed of at least two different components, the drug and a nontoxic cocrystal former, held together by freely reversible, noncovalent bonds, predominantly hydrogen bonds [329]. Cocrystals are a strategy for poorly soluble neutral compounds to improve their solubility and dissolution rate, similar to salt formation, regardless of ionizable groups [267,268]. It is important to screen carefully for appropriate cocrystal formers, to test both their solution stability and dissolution behavior, and to understand possible conversions of solids that could take place on contact with solvents. Coformers with lower aqueous stability appear to form cocrystals with better solution stability; however, there are still many uncertainties, and cocrystals were found to enhance, slow down, or not affect the dissolution rate of a drug at all. The screening for cocrystals is usually not done in discovery and often, only started in early development after other approaches to improve a drug's solubility, BA, or stability failed or after efforts to crystallize drugs by standard approaches were unsuccessful. Formulators should also be aware of unintentional cocrystal formation with excipients that sometimes occur in formulation, for example, with saccharin, benzyl alcohol, or parabens [330]. A comprehensive review summarizing the current status of cocrystal research and their characterization has been published recently by Schultheiss and Newman [128].

16.6.3.3.3 Hydrates. Solvates are crystalline drug solvent adducts. Adducts with water, hydrates, are a common phenomenon, and almost 50% of the pharmacopeial compounds, salts, and nonsalts are known to form hydrates [331]. Unidentified hydration or dehydration processes may result in unexpected and variable behavior of drugs and drug products during processing and storage and affect a number of factors such as chemical and physical stability, BA, wetting, dispersibility, or compactibility. Unintentional hydrate formation is often an issue in early phases of development when aqueous suspension vehicles are used for animal dosing, when the preparation/storage conditions of drugs are not well controlled or when water-based processes such as wet granulation or spray drying are used for drug processing. In many cases, the solubility and/or dissolution rate of hydrates is lower than that of the anhydrate [126], and hence exposures in *in vivo* studies can drop significantly [270]. These issues are presumably more important for LS than for HS compounds, and it is important to address hydrate formation early on; stable hydrates may already be identified in early phases by simple, longer term, slurry experiments in water with subsequent Raman or XRPD analysis of the solid.

16.6.3.3.4 Cyclodextrins. Improved dissolution of LS drugs and an increase in apparent solubility can also be achieved by complexation of drugs with CD (Fig. 16.9). CDs are (α -1,4)-linked oligosaccharides containing typically 6-10 α -D-glucopyranose units. They take the shape of a truncated cone or torus with the hydroxyl functional groups oriented to the exterior and the skeletal carbons and ethereal oxygens to the interior of the cone. Thus a hydrophobic cavity is formed in the CDs, which can take up poorly soluble molecules. The efficiency of these inclusion complexes depends on the size of the cavity and the properties of the guest molecule. Guest and host molecules are in a dynamic equilibrium, and complexation efficiency can, positively or

negatively, be affected by excipients or constituents of intestinal fluids as mentioned in Section 16.5.1.3 and reviewed by Brewster and Loftsson [251]. CDs often also increase the apparent solubility of compounds as discussed later (Section 16.6.4.3), the solubility profile depending on the type of complex formed and on its stoichiometry [332]. In addition, CDs can improve chemical and physical stability, mask bad taste or odor, reduce volatility, convert oils or liquids into solids, or reduce side effects. Complexes can be prepared by a variety of methods, including kneading, evaporation, and freeze drying [333]. In case of solid CD–drug complexes, drugs are molecularly dispersed and have no own crystal structure. The solid complexes may be crystalline or amorphous. The exterior of CD–drug complexes is hydrophilic, and typically, they dissolve very rapidly. Since CDs then keep the drug in solution for an extended period, an increase in drug absorption is often observed in their presence [333–335]. On the contrary, CDs are also reported to reduce drug permeability both *in vitro* and *in vivo*, although they markedly decrease UWL permeability [231]. Therefore, a trade-off exists between the increase in solubility and the decrease in permeability, and hence, the overall *in vivo* effect of CDs on absorption will also presumably depend on the local CD concentration and the binding constant of the complex.

16.6.3.3.5 Solid Solutions and Dispersions. In solid solutions and solid dispersions, an LS drug is embedded in an inert solid hydrophilic polymer carrier such as Polyethylenglykol (PEG), Poly-Vinyl-Pyrrolidon (PVP), Polyvinyl acetate (PVA), Hydroxypropyl Methycellulose (HPMC), or sugars to improve its dissolution rate and/or apparent solubility. In solid dispersions, drug is distributed as fine colloidal crystalline or amorphous particles in the polymer. In contact with aqueous media, the drug is released as very fine particles with a high surface area, which facilitates a rapid dissolution. In solid solutions, the drug is mixed with the polymer at the molecular level to form a real solution. In contact with water, the drug is then dissolved parallel to the polymer. Drug–polymer dispersions or solutions can be prepared by dispersing/dissolving drug in molten polymer or in a common solvent followed by resolidification of the melt or by solvent evaporation, respectively. Known challenges with these techniques are heat-labile drugs, which can not be used in a melt process, or the difficulty to identify a common solvent for both the hydrophilic carrier and the hydrophobic drug. Other common preparation techniques are physical mixing of the polymer and drug [273] and cogrinding [274]. The stability of such systems can be an issue. Depending on drug load, storage conditions, and formulation composition, dissolved compound in solid solutions or completely or partially amorphous drug generated during preparation of solid dispersions may crystallize with time in the matrix. Therefore, appropriate polymers have to be selected with care to avoid transformations during storage. Although screening systems for solid dispersion in discovery became available recently [160], these formulation approaches are typically only used in special cases in early and late development if other, less risky approaches fail to achieve a sufficient exposure.

16.6.4 Solution Formulation Strategies

All formulations described in the previous section contain the drug in solid form. This section summarizes formulation approaches that present drug in the dissolved state to the GIT, and hence no dissolution step is required for absorption (Fig. 16.9). Solubilization is achieved by pH adjustment, cosolvents, cyclodextrins, surfactants

and lipids, or combinations thereof. These approaches are often preferred in discovery and early development phases as the influence of the initial solid state properties of compounds on PK/PD studies can be neglected, and hence it is believed that compounds are easier to compare. Here, it is often overlooked that these approaches address kinetic solubility (Section 16.5.3.1) and that compounds may precipitate on dilution of the formulation or digestion of formulation constituents in the GIT. The overall *in vivo* performance of a drug would then be governed by both its precipitation kinetics and the dissolution rate of its precipitate; the latter depending on the kind of precipitate (amorphous or crystalline), the particle size, and the particle distribution (finely dispersed or agglomerated). Therefore, it is important to evaluate the precipitation tendency of drug formulations in artificial intestinal media (simulated gastric fluid (SGF), FaSSIF, FeSSIF) as well as the nature and dissolution behavior of the precipitates before drug candidates can really be compared and ranked. This is not always feasible in early phases; however, scientist should be aware of these issues.

16.6.4.1 pH Adjustment. Adjustment of pH can be used to solubilize compounds with ionizable groups. The solubility of these compounds is usually strongly pH dependent, and once their pH–solubility profile has been determined, it can be estimated whether or not a given dose can be given orally as solution by this approach. The pH of the final solution can be in the range of 3–8 for oral delivery. For the extreme pH values, high buffering capacities should be avoided, since this may cause irritations in the GIT because of unphysiological pH values, in particular, after repeated dosing. *In vivo*, solutions of weak bases may precipitate in the small intestine if they are not absorbed rapidly enough and the concentration of the unionized form exceeds their intestinal solubility. Similarly, weak acids may precipitate at low pH in the stomach; however, there is a high chance that they dissolve again further down in the GIT at higher pH. *In vitro*, tests are available to study this behavior [285].

16.6.4.2 Cosolvents. Cosolvent systems are another popular approach for oral delivery of drugs in solution, which may also be used for parenteral formulations. In particular, in early PK studies, LS compounds are often solubilized in cosolvents such as ethanol, PEG300, PEG400, propylene glycol, glycerin, Dimethylacetamide (DMA), N-Methyl-2-pyrrolidone (NMP), or DMSO [301]. Cosolvents are used alone, are mixed with water with or without pH adjustment, or are combined with cyclodextrins or surfactants. Combinations of cosolvents are also used to reduce vehicle toxicity. In addition to their solubilizing activity, pure cosolvents may also increase the stability of drugs, for example, against hydrolysis [336]. Uncontrolled precipitation may occur on dilution of cosolvent formulations with aqueous media, and a semilogarithmic relationship exists among total drug solubility, drug solubility in water, and the cosolvent volume fraction [301]. The increase in the extent of oral absorption that is often observed with cosolvent formulations may be explained by both the generation of temporary supersaturated solutions and the high energy precipitates (Section 16.6.3.2). Ideally, the precipitates should consist of prewetted, finely dispersed, and amorphous solids with very small particle sizes to achieve maximum dissolution rates.

16.6.4.3 Solution Formation Using Cyclodextrins. Solid inclusion complexes of drugs and cyclodextrins have been discussed before in Section 16.6.3.3.4. Drugs that interact with CDs may also be formulated as solutions for oral or parenteral

administration. Many drugs favorably bind to β -CDs; however, since its solubility is limited, usually, complexes with the more soluble hydroxypropyl- β -cyclodextrins (HP- β -CDs) and sulfobutylether- β -cyclodextrins (SBE- β -CDs) are preferred for solutions [251]. The effect of CDs on the oral absorption of a drug will depend on amount administered, binding strength, dilution, and presence of molecules competing for binding. If a drug is bound strongly to CDs and dilution in the intestine is low, lower amounts of free drug may be available for absorption than in situations in which the drug rapidly dissociates from the CDs or is displaced, for example, by bile salts. However, in the latter case, the risk for drug precipitation also increases.
